(Received 13 November 1997; accepted 7 January 1998)

Quadratic electro-optic effects (dc or low frequency Kerr effect) of bacteriorhodopsin dispersed in dried gelatin thin films are examined in the near resonance region at three wavelengths: 633, 647, and 676 nm. The films show relatively large quadratic electro-optic effects compared to other molecular dispersed systems. The purple membrane is fixed within the polymerized gelatin matrix, and we show that the electronic contribution to $\gamma$ dominates over possible orientational contributions. At 676 nm, the quadratic electro-optic coefficient $s_{333}(-\omega;0,0,\omega)$ is $6.7 \times 10^{-20} \text{m}^2/\text{V}^2$ and the third order nonlinear susceptibility $\chi^{(3)}(-\omega;0,0,\omega)$ is $7.0 \times 10^{-13} \text{cm}^4/\text{statCoulomb}^2$, with both values obtained for a protein concentration of $6.9 \times 10^{18} \text{cm}^{-3}$. The orientationally averaged second molecular hyperpolarizability $(\gamma(-\omega;0,0,\omega))$ determined from the quadratic electro-optic coefficients at 676 nm assuming an Onsager ellipsoidal local field factor is $(10.8 \pm 5.1) \times 10^{-32} \text{cm}^2/\text{statCoulomb}^{-2}$. The $(\gamma(-\omega;0,0,\omega))$ value increases roughly tenfold when the probe wavelength is decreased to 633 nm. The behavior of $(\gamma(-\omega;0,0,\omega))$, when fit to a two-state model, predicts that $\gamma(-\omega;0,0,\omega)$ is strongly enhanced via type III processes. Thus, the magnitude of $\gamma(-\omega;0,0,\omega)$ is dominated by a term $(\Delta \mu_{10} \times \mu_{10}^{-1})/(\omega_{10} - \omega)^2$, where $\Delta \mu_{10}$ is the change in dipole moment, $\mu_{10}$ is the transition moment, and $\omega_{10}$ is the transition energy of the lowest-lying allowed $1B_u^+\pi$-like $\pi, \pi^*$ state. We calculate that $\Delta \mu_{10}$ is $12.8 \pm 1.2 \text{ D}$, in good agreement with previous Stark and two-photon experimental values. Time-dependent Hartree–Fock methods based on the MNDO Hamiltonian yield reasonable agreement with experiment, underestimating $\gamma(-\omega;0,0,\omega)$ by factors of only 2–4, with the error increasing as the frequency approaches resonance.

I. INTRODUCTION

Bacteriorhodopsin (BR, M.W.≈26,000) is the light transducing protein found in the purple membrane formed in the cell wall of the bacterium, Halobacterium salinarium. The physiological function of this protein is to produce energy for converting ADP to ATP by pumping protons from the cytoplasmic to the extracellular side of the cell wall. The resulting pH gradient across the cell wall generates a proton motive force for synthesizing ATP. The proton pumping process is mediated by a complex photocycle which is illustrated in Fig. 1. When bacteriorhodopsin first absorbs light, it converts from the dark-adapted form to a light-adapted form (bR), which contains only an all-trans protonated Schiff base chromophore. Unless specified otherwise, all of our experiments and all similar studies in the literature were carried out on the light-adapted form.

Bacteriorhodopsin is known to exhibit large optical non-linearities, due in part to the large difference between the dipole moment in the ground state and that in its lowest-lying, strongly allowed excited state. The first measurement of $\beta$ by Huang et al. gave a value of $2500 \times 10^{-30} \text{cm}^5/\text{statcoulomb}^{-1}$, approximately ten times larger than other organic chromophores of comparable conjugation length. Subsequent studies yielded a comparable value of $2250 \pm 240 \times 10^{-30} \text{cm}^5/\text{statcoulomb}^{-1}$ based on an analysis of the two-photon double resonance spectrum. Analysis of the two-photon data also indicate that $\gamma$ should be relatively large, due in part to the large change in dipole moment upon excitation (type III enhancement).

In this study, we report the direct observation of $\gamma$ of bR dispersed in dried gelatin thin films in the near resonance region. Our experimental method is based on the technique proposed by Schildkraut for measuring linear electrooptic effects by using a reflection geometry. In this experiment, gelatin films containing bR were formed on ITO covered glass substrates and Au electrodes were deposited on the surface of the gelatin films. A low frequency electric field is applied to the gelatin film to induce birefringence. Low intensity laser light is then directed onto the film through the ITO coated glass substrate. The laser light propagating inside the gelatin film is then reflected back by the surface of the Au electrode. The electromagnetic field associated with the laser light is modulated with a change in the phase difference between s- and p-polarized component caused via linear electro-optic effects and/or quadratic electrooptic effect (also referred to as dc or low frequency Kerr effects).
Gelatin has been known to have a cross-linked, collagen-like structure with hydrogen bonds. When purple membrane is immersed in the gelatin matrix, the purple membrane is considered to be spatially fixed. The interaction between the host molecule and the gelatin matrix via the hydrogen bonds is expected to play a role in preventing induction of molecular orientation under strong modulation field. For example, Ho et al. investigated linear electro-optic effects of para-nitrophenol in a gelatin matrix and observed that the gelatin matrix maintained poling stability. Thus, we conclude that orientational contributions to the measured electro-optic effect can be ignored. Our experimental results provide support for this conclusion. By analyzing the wavelength dependence of $\gamma$, we gain insight into the electronic origin of the large second order hyperpolarizability of bacteriorhodopsin.

II. EXPERIMENT

A. Sample preparation

Purple membrane was isolated from the strain S9-P of Halobacterium salinarium by using the following procedure. The bacterium was collected by spinning down the culture containing the bacterium in a Beckman JA-10 rotor at 5000 rpm (15 000 g) for 10–15 min, then resuspending in distilled water. The total volume of the suspension was approximately 500 mL. We then added 0.15 mg/mL of DNase I type IV (Sigma D-5025) and 0.25 g of MgSO$_4$ to the suspension to digest the DNA contaminant. The suspension was left over night with gentle stirring at ambient temperature, and the cell debris was removed by spinning the sample down using a Beckman JA-17 rotor at 5000 rpm for 5 to 10 min.

The supernatant and purple membrane were saved and spun down in a 45 Ti rotor at 32 000 rpm (109 000 g) for 35 min at 4 $^\circ$C. Pellets of purple membrane which formed at the bottom of the centrifuge tubes were washed via resuspension in de-ionized water, followed by centrifugation as described above. This procedure was repeated until the supernatant became clear. Brownish cell debris found in the pellet at bottom of centrifuge tubes was removed mechanically.

The gelatin thin films dispersed with the purple membrane were prepared as follows. Gelatin (gelatin type A from porcine skin [CAS # 9000-70-8], Sigma Chemical Co., used as received) was dissolved in deionized water by heating to 60–65 $^\circ$C for 40 min in a round bottom flask equipped with a water condenser on a water bath. The concentration of gelatin was 10 w/w% in de-ionized water. After the gelatin was completely dissolved, the solution was filtered with a syringe filter (pore size 5 $\mu$m Micron Separations Inc.) while the solution was still hot. The suspension of bacteriorhodopsin in deionized water was spun down in the Beckman 45 Ti rotor (32 000 rpm, 109 000 g for 30 min) to yield a pellet of purple membrane. The pellet was resuspended in a minimal amount of deionized water. Then the suspension was sonicated for 30 min. The sonicator tip was directly immersed in the suspension for efficient sonication.

The gelatin solution and protein suspension were filtered with a syringe filter (AcetatePlus Membrane, pore size 5 $\mu$m, diameter 25 mm, Micron Separations Inc.), heated to 60 $^\circ$C, and then mixed with gentle stirring for about 30 min while maintaining the temperature at 60 $^\circ$C. The resulting mixture was coated onto an indium tin oxide (ITO) coated BK-7 glass substrate via the spin coating method. The thickness of the ITO coating was approximately 1000 Å yielding a resistivity of about 1 k$\Omega$ cm. Spin coating was carried out by pipetting 200–250 $\mu$L of the protein:gelatin mixture onto the preheated ITO coated substrate so that the mixture covered the surface as uniformly as was possible. The substrate was then transferred to the spin coating apparatus, and the thickness of the final film was controlled by adjusting the rotational speed of the spin coater. By using this procedure, film thicknesses ranging from 3 to 15 $\mu$m were achieved.

After the films had formed on the ITO covered glass substrates, they were dried in a closed container, in which the relative humidity was maintained at 80% to 85% and temperature was maintained at 25 $^\circ$C for two days. The humidity was controlled by placing a beaker containing a saturated KCl solution inside the container.

The film thickness was measured by taking transmittance spectra from the visible to the near IR region. An interference pattern was found in the transmittance spectra when the surface quality of the films was high, and the films were of uniform thickness. All further optical studies were carried out only on those films which satisfied the above two criteria. The film thickness was determined from the interference pattern by using the following equation:

$$l = \frac{\Delta m}{2 \sqrt{n^2 - \sin^2 \theta}} \left( \frac{1}{1/l_2 - 1/l_1} \right),$$

where $l$ is the film thickness, $\Delta m$ is the number of peaks (or valleys) in the interference pattern, $l_1$ is the longest wavelength in the interference pattern, $l_2$ is the shortest wavelength in the interference pattern, $\theta$ is the incident angle of a probe beam and $n$ is the refractive index of the films ($n$
electrooptic effects

...about 65% relative humidity. Measurements, the films were stored for two days at ambient temperature and about 65% relative humidity. Prior to carrying out our optical measurements, the films were stored for at least five days. To remove the distortion, the films were placed in the humidity and temperature controlled container provided a synchronized signal to the ac power supply. The high voltage power supply was driven well below its rms capacity to avoid nonsinusoidal behavior and no bias was added to the signal to avoid creating a net orientational (poling) applied field.

C. Signal analysis

In the weak poling limit, the refractive index change associated with an external applied electric field can be written for ordinary and extraordinary rays as follows:

\[ \Delta n_o = \frac{1}{2} n_o^3 (r_{113} E_3 + s_{1133} E_3 E_5), \]

(2a)

\[ \Delta n_e = \frac{1}{2} n_e^3 (r_{333} E_3 + s_{3333} E_3 E_5), \]

(2b)

where \( r_{113} \) and \( r_{333} \) are the linear electrooptic coefficients measured along in-plane and film normal directions, respectively, and \( s_{1133} \) and \( s_{3333} \) are the quadratic electrooptic coefficients measured along the in-plane and film normal directions, respectively. The Schildkraut derived expression for the degree of the phase modulation in the reflection geometry is

\[ \Gamma = \frac{4 \pi}{\lambda} l \Delta n \frac{\sin^2 \alpha}{\cos \alpha}, \]

(3a)

\[ \Delta \Delta n = \Delta n_e - \Delta n_o. \]

(3b)

Assuming Kleinman’s symmetry holds \( (r_{333} = 3r_{113}, s_{1133} = 3s_{1133}) \) and \( n_o \sim n_e \sim n \), Eq. (3a) becomes

\[ \Gamma = \frac{4 \pi n_0^3}{\lambda} [r_{113} E_3 + s_{1133} E_3 E_5] \frac{\sin^2 \alpha}{\cos \alpha}. \]

(4)

When the modulation field can be represented as a simple ac field \( E_m = (V_m/l) \cos \Omega t \), the relationship between the phase shift, \( \Gamma \), and the modulated laser light intensity ratio, \( I_{ac}/I_{dc} \), can be calculated as follows:

\[ I_{ac}/I_{dc} \]
where \( l \) is film thickness, \( V_m \) is applied voltage, \( I_{ac} \) is degree of modulation and \( I_{dc} \) is defined as the dc signal obtained by subtracting the dc level with the quarter wave plate with applying no modulation voltage from the dc level without the quarter wave plate with applying no modulation voltage. The dc signal thus corresponds to 50% transmittance, and the \( \pi/2 \) phase biasing has been added into Eq. (5). The phase biasing is achieved by placing the quarter wave (\( \lambda/4 \)) plate into the optical path as shown in Fig. 2. The term \( \Delta n_{abs} \) arises from the absorption change of the medium and does not depend on the modulation field. The system is considered to be isotropic, and thus the term involving \( r_{113} \) is either not detectable or negligible compared to the term involving \( s_{1133} \). Only the term depending on \( \cos 2\Omega t \) is detected by the lock-in amplifier at the second harmonic frequency of the modulation field. The degree of modulation at the second harmonic frequency is defined as

\[
\frac{I_{ac}^{2\Omega}}{I_{dc}} = -\Delta n_{abs} \cos 2\Omega t = \frac{2\pi n^3 s_{1133} V_m^2 \sin^2 \alpha}{\lambda l \cos \alpha} \cos 2\Omega t,
\]

(6)

where \( \Delta n_{abs} \) is the amplitude of the phase shift modulation. The relation between the effective propagation angle, \( \alpha \), and the incident angle, \( \theta \), is given by Snell’s law

\[
\sin \theta = n \sin \alpha.
\]

(7)

Considering Eq. (7) and assuming that both the modulation field and the modulated light amplitude are measured as rms amplitudes, Eq. (6) reduces to

\[
s_{1133}^{expt} = \frac{3\lambda I}{2\sqrt{2}\pi (V_m^{rms})^2} \frac{\sqrt{n^2 - \sin^2 \theta}}{n^2 \sin^2 \theta} \frac{I_{ac}^{2\Omega, expt}}{I_{dc}}. 
\]

(8)

III. RESULT AND DISCUSSION

A. Quadratic electrooptic effects observed in the gelatin films containing bR

Figure 3 shows a typical electrooptic response from bacteriorhodopsin dispersed in gelatin film obtained using 632.8 nm laser radiation. Signal amplitudes at the second harmonic frequency (1 kHz) were typically 2 to 3 orders of magnitude larger than those at the fundamental frequency (500 Hz). Signals at a fundamental frequency based on linear electrooptic effects were not detectable in most cases, because the protein samples are highly homogeneous and isotropic. However, the quadratic modulation voltage dependence of the signals at a second harmonic frequency were distinct and the raw signal intensity in rms voltage was on the order of 0.1–10 \( \mu \)V, levels readily observable by the digital lock-in amplifier. The modulated signal amplitudes normalized with the dc components were on the order of \( 10^{-4} – 10^{-2} \).

Three consecutive experiments were carried out for each sample at each wavelength (Fig. 3). Spectrophotometric studies were carried out to verify that the protein remained light-adapted during the experiment. Contributions to the quadratic electro-optic effects from gelatin itself were negligible. The normalized modulated light intensities were replotted against the quantity

\[
\frac{(\text{rms amplitude of modulation voltage})^2}{\text{wavelength} \times \text{film thickness}}
\]

From the slopes of the curves obtained with this analysis, \( s_{1133} \) was calculated via Eq. (8). Figure 4 shows an example of the normalized intensity-normalized quadratic voltage plot.
at 632.8 nm for a range in bacteriorhodopsin concentration from $6.9 \times 10^{17}$ cm$^{-3}$ to $6.9 \times 10^{18}$ cm$^{-3}$. The curves shown in Fig. 4 were successfully fitted with straight lines with good correlation between the above two quantities. The same curve fitting procedures were used to analyze the data at 647.1 and 676.4 nm.

Figure 5 shows the bacteriorhodopsin concentration dependence of the quadratic electrooptic effects measured at several wavelengths. These data indicate that the quadratic electrooptic effects are approximately linear with respect to concentration of bacteriorhodopsin within the concentration range investigated here. This observation implies that the second molecular hyperpolarizability can be determined from the slopes of these curves. We can thus conclude with confidence that the protein, and not the gelatin matrix or other components along the light path, is responsible for the signal. It is thus possible to equate the measured value of $\chi^{(3)}$ to the molecular $\gamma$ via the relation $\chi^{(3)} = NL(\gamma)$, where $N$ is the concentration of the protein and $L$ is a local field correction.

Neither the linear nor the quadratic electrooptic effect is expected to be dependent on the incident light intensity, but dependent only on the amplitude of the modulated electric field. However, the modulated light intensities with the quadratic electrooptic effects detected at 633 nm are proportional to the logarithm of the photon density of the incident light while the signal levels measured at 647 and 676 nm are invariant to photon density as shown in Fig. 6.

One possible explanation for the anomalous signal enhancement at 633 nm is an increased population of the $O$ state of bacteriorhodopsin, which has an absorption maximum at $\approx 645$ nm (see Fig. 1). Bacteriorhodopsin has a sufficient absorptivity at 633 nm to yield a small population of photocycling molecules within the irradiated volume element, and the $O$ state has a relatively long lifetime ($\sim 4$ ms). We conclude that the quadratic electrooptic effect is likely enhanced anomalously by $O$ state interference. Regardless of the origin of the effect, we removed the interference by extrapolating our data back to low light levels where such interference was minimal.

**B. Calculation of $\gamma$ from $s$**

The third-order nonlinear susceptibility is related to the quadratic electrooptic coefficient by the following relationship:

$$\chi_{1133}^{(3)}(-\omega;0,0,\omega) = \frac{n^4}{12\pi} s_{1133}(-\omega;0,0,\omega) \text{ (cgs-esu)}.$$  

(9)

A relation between the macroscopic third order nonlinear susceptibility of the films and the second molecular hyperpolarizability of the protein can be derived by taking local field factors into account. However, the choice of a local field factor is not obvious, because we are dealing with a chromophore imbedded inside a complex binding site (see Fig. 7).\cite{25} For this reason, we will investigate here a variety of local field factors. The local field factor introduced by Onsager has been used extensively for studies of nonlinear optical properties of organic molecules (Appendix A). The Onsager’s local field factor was derived assuming that the molecule is a dipole placed in a virtual spherical cavity in a continuous dielectric matrix and the local field is a sum of the field inside the cavity and the reaction field resulting from an interaction between the dipole moment of a molecule in the cavity and a polarization induced in surrounding matter by an external field. However, the retinal chromophore considered here is a rod shaped polyene. Hence, an ellipsoidal cavity is considered to be more suitable in this case (Fig. 7).\cite{26} The expressions of the local field factors for the ellipsoidal cavity at a static field $f^{(0)}_{\text{ellipse}}$ and at an optical frequency $f_{\text{ellipse}}$ are given in (A6) and (A7) in Appendix A, respectively. Also, the expressions of the local field factors for the spherical cavity at a static field $f^{(0)}_{\text{sphere}}$ and at an optical frequency $f_{\text{sphere}}$ are given in (A8) and (A9) in Appendix A, respectively. For example, $f_{\text{ellipse}}^{(0)}$ is given as follows:
For comparison, the Lorentz-type local field factors were also considered as account. For example, the Lorentz-type local field factors were derived by Lorentz. In the Lorenz's approximation, the reaction field is not taken into account. For comparison, the Lorenz-type local field factors for ellipsoidal and spherical cavities were also considered as the local field correction. The local field factors derived using the Lorenz approximation are given in (A14) and (A15) in Appendix A. For example, $f^{(w)}_{\text{sphere}}$ is given as follows:

$$f^{(w)}_{\text{sphere}} = \frac{\varepsilon_2(\omega) + 2}{3}.$$  \hfill (A15)

The permittivity of gelatin measured at 1 kHz ($\varepsilon_2(0) = 2.07$) was used as the static field permittivity of the polymer matrix. The refractive indices of the protein and the gelatin matrix at optical frequencies were taken from Song et al.\textsuperscript{27} and were used for the calculation of the permittivities assuming $\varepsilon_1(\omega) \equiv n^2 = (1.53)^2$ for bacteriorhodopsin and $\varepsilon_2(\omega) \equiv n^2 = (1.54)^2$ for gelatin. The refractive index of opsin (the protein without the chromophore) was assumed to be equal to that of the gelatin matrix based on the experimental result for the effective dielectric constant of the protein in the $M$ state ($\varepsilon_2(0) = 2.2$) obtained by Dioumaev et al.\textsuperscript{28} The resulting local field factors are tabulated in Table I.

The molecular hyperpolarizability, $\gamma$, can now be related to the third order nonlinear susceptibility, $\chi^{(3)}$, by using the following relationship:

$$\chi^{(3)}_{ijkl}(\omega;0,0,\omega) = N f^{(0)} f^{(w)} f^{(w)} \langle \gamma(-\omega;0,0,\omega) \rangle_{ijkl},$$  \hfill (10)

where $\langle \gamma(-\omega;0,0,\omega) \rangle$ is an orientational average of $\gamma$ over the molecular coordinates and $N$ is concentration of the guest molecule. The subscripts $i$, $j$, $k$, and $l$ denote film coordinates and $\chi^{(3)}_{ijkl}(\omega;0,0,\omega)$ is a tensor component of $\chi^{(3)}$. The calculation of $\langle \gamma(-\omega;0,0,\omega) \rangle$ is discussed in Appendix B. If the films are isotropic, $\langle \gamma(-\omega;0,0,\omega) \rangle_{3333}$ is also an average value over the film coordinates, and the average value of $\gamma$ over the film coordinate is given by

$$\langle \gamma \rangle = \langle \gamma \rangle_{3333} = 3 \langle \gamma \rangle_{1113}.$$  \hfill (11)

Thus, $\gamma(\omega;0,0,\omega)$ can be calculated from $\chi^{(1)}_{\text{1133}}(\omega;0,0,\omega)$ by using Eqs. (10) and (11). The results are presented in Table IV. We consider the values for the Onsager elliptical local field factors to be the most experimentally relevant. The difference between the Onsager and Lorentz elliptical values, are, however much smaller than the experimental error. It would seem clear from an examination of Fig. 7 that an elliptical cavity is much more appropriate than a spherical cavity approximation.

C. Analysis with the two-state model

Kuzyk et al. have derived expressions for the second order induced orientational effects $s_{1133}^\text{or}$ and the orientational effect $s_{1133}^\text{ot}$ as follows:29

\begin{equation}
S_{1133}^\text{or} = \frac{4\pi N \beta_{222} \mu^2}{9 \times 10^8 \times 10^{-5}} \times (14 - 50A_2 + 36A_4),
\end{equation}

\begin{equation}
S_{1133}^\text{ot} = \frac{1}{9 \times 10^8} \times \frac{16 \pi \rho \alpha^2}{k_B} \times (7 + 5A_2 - 12A_4).
\end{equation}

In these formulas, quantities with * denote local field corrected quantities and $A_2$ and $A_4$ are orientational order parameters. The factors $A_2$ and $A_4$ are zero for an isotropic system, $k_B$ is a microscopic elastic modulus constant in dyn cm, and $k_B$ is defined as a force constant of the restoring force $F$ acting on the chromophore upon applying an electric field

\begin{equation}
F = \frac{k_B}{2} (\theta - \theta_0)^2.
\end{equation}

In (13), $\theta - \theta_0$ is an angle variation between the direction of the applied electric field and the static dipole moment of the chromophore before and after applying the electric field. Alternatively, $k_B$ can also be estimated by multiplying the molecular volume of all-trans retinal, $V$, by the bulk modulus of the gelatin polymer, $K$, assuming that the purple membrane patches are strongly interacting with the gelatin matrix. For the present study, we use an ellipsoidal cavity volume instead of the molecular volume (see discussion below). Equations (12) and (13) were evaluated assuming $A_2 = A_4 = 0$ (isotropic case) based on a bacteriorhodopsin concentration of 6.9×10$^{-18}$ cm$^{-3}$. The results are tabulated in Table II. All quantities not evaluated by us are available from the literature30–33 and all relevant parameters are tabulated in Table III. Subtraction of $S_{1133}^\text{ot}$ and $S_{1133}^\text{or}$ from the experimentally measured value of $S_{1133}$ should give a pure electronic contribution to the quadratic electrooptic effect. The total orientational correction for $S_{1133}$ is consequently 8.5×10$^{-26}$ m$^2$/V$^2$, which is negligible compared to the experimental result of $S_{1133}$ obtained for this sample, 6.7×10$^{-20}$ m$^2$/V$^2$. Therefore, the orientational contribution is negligible, and will be ignored in subsequent analyses.

Our experimental values of $\gamma$ as a function of energy can be fit with good precision by using a very simple two variable nonlinear equation: $A(\omega_0 - \omega)^3$, where $\omega$ is the photon frequency and $A$ and $\omega_0$ are the two variables. For reasons that will be clear from the subsequent discussion, this behavior is an indication that a single excited electronic state dominates the resonant enhancement of $\gamma$. This permits the use of a simple two level model of the process

\begin{equation}
\gamma_{1'1',1'(\omega'0'; \omega_0, \omega_2, \omega_3)} = 4K(\omega_0, \omega_1, \omega_2, \omega_3)(\hat{h})^{-3}I_{1'1';1',1}(\omega_0, \omega_1, \omega_2, \omega_3) - \frac{|\langle g | \mu_{1',1'} | n \rangle|^2 |\langle n | \mu_{1',1'} | g \rangle|^2}{(\omega_0 - \omega_0)(\omega_0 - \omega_1)(\omega_0 - \omega_2)}.
\end{equation}

where $\omega_0 = \omega_0$ corresponds to a transition frequency from a ground state to an excited state of interest, $I$ denotes the average of all terms generated by permuting $\omega_0, \omega_1, \omega_2, \omega_3$, and $K$ is a numerical factor that depends on the presence of zero frequencies and repeated frequencies in the set $\omega_0, \omega_1, \omega_2, \omega_3$. In addition, $\mu_{1',1'}$ is a ground state dipole moment of the chromophore along $i'$ direction in the molecular coordinate, and $|n \rangle$ and $|g \rangle$ denote state vectors.
for the \( n \)th state and a ground state of the chromophore, respectively. Equation (14) is a reduced expression of Eq. (B6) given in Appendix B.

Because the barred matrix element in Eq. (14) is defined as

\[
\langle n | \mu_{i,j,k}^2 \text{ or } \mu | n \rangle = \langle n | \mu_{i,j,k}^2 \text{ or } \mu | n \rangle - \langle g | \mu_{i,j,k}^2 \text{ or } \mu | g \rangle,
\]

(15)

this term represents the dipole moment difference \( \Delta \mu_{g,n} \) between the ground state and the excited state. Also, \( \langle g | \mu_{i,j,k}^2 \text{ or } \mu | n \rangle \) is the transition moment associated with the \( g \to n \) transition, and is thus proportional to the oscillator strength of the chromophore. Equation (14) can now be reduced to the simple form

\[
\gamma_{10}(\omega; 0, 0, 0) = \frac{\Delta \mu_{10}^2 \times \mu_{10}^2}{(\omega_{10}^2 - \omega^2) + \omega_0^2} - \frac{\mu_{10}^4}{\omega_{10}^6 (\omega_{10}^2 - \omega)^2 + \omega_0^6} + \text{cross terms},
\]

(16)

where the subscript “\( 1 \)” is used to represent the excited state, “\( 0 \)” represents the ground state and a damping term, \( \omega_D \), is added to allow the use of this equation in fitting the experimental data (see discussion in Ref. 12). The cross terms that appear in Eq. (16) approximately cancel out and can be safely ignored.\(^\text{25}\) The most appropriate value for \( \omega_0 \) is 250 cm\(^{-1}\), an upper limit to the homogeneous linewidth in bR\(^\text{14}\) [see also discussion following Eq. (36) in Ref. 12]. Fortunately, our subsequent calculations are not overly sensitive to assignment of the damping term provided this term is below 1000 cm\(^{-1}\). It was our hope that we could use Eq. (16) to examine the molecular electronic properties responsible for the large second order hyperpolarizability of bacteriorhodopsin. We therefore used weighted nonlinear least-squares procedures to fit Eq. (16) to the Onsager elliptical experimental data. The weighting factors of the data points were assigned to be linearly proportional to the protein concentration. However, as might be anticipated by an examination of Eq. (16), the values of \( \mu_{10} \) and \( \Delta \mu_{10} \) are highly correlated. That is, a unique simultaneous fit of these two variables is not possible. We explore their interrelationship in Fig. 8, which presents the errors contours as a function of the oscillator strength (y axis) and the change in dipole moment (x axis). The minimum error contour is shown with a gray dotted line, and is given by the equation:

\[
\Delta \mu_{10}(D) = 0.5515 \times f_{10}^{1.274} + 11.386 \times f_{10}^{-0.4943} - 0.3678.
\]

(17)

Two-photon studies indicate that there are in fact two allowed low-lying states, the lowest energy \( 1B_u^{\#} \)-like state (\( \lambda_{\text{max}} = 568 \text{ nm, } f = 0.8 \pm 0.07, \Delta \mu = 13.5 \pm 0.8 \text{ D} \)) and a higher energy \( 1A_g^{\#} \)-like state (\( \lambda_{\text{max}} = 488 \text{ nm, } f = 0.3 \pm 0.15, \Delta \mu = 9.1 \pm 4.8 \text{ D} \)).\(^\text{12}\) These results suggest that in the near-resonant region, the \( 1B_u^{\#} \)-like state is the dominant contributor to \( \gamma(\omega; 0, 0, 0) \). This conclusion follows from considerations of energy, oscillator strength, and dipole moment change, all three of which favor participation of the \( 1B_u^{\#} \)-like state in enhancing \( \gamma(\omega; 0, 0, 0) \). Simulations based on a three state model and the above parameters indicate that the contribution of the \( 1B_u^{\#} \)-like state relative to the \( 1A_g^{\#} \)-like state increases from \( \sim 100 \) at 676 nm to \( \sim 125 \) at 633 nm. This is further evidence that the two-state model is adequate for analyzing the results in this region of the spectrum. The two state model predicts \( \Delta \mu_{10} = 12.8 \text{ D} \) and \( \omega_{10} = 2.117 \text{ eV} \) (Table IV) assuming \( f_{10} = 0.8 (\mu_{10} = 9.98 \text{ D}) \).\(^\text{12}\) If we include the error range in \( f_{10} \) and experimental error in our experimental measurements, the error contour analysis presented in Fig. 8 predicts that the dipole moment difference between the \( 1B_u^{\#} \)-like \( \pi, \pi^* \) state and the ground state is \( 12.8 \pm 1.2 \text{ D} \). Our assignment is in excellent agreement with the value determined from Stark measurements (12.4 D)\(^\text{35}\) and two-photon spectroscopy (13.5 \pm 0.8 D).\(^\text{12}\) We anticipate that the close agreement between the present measurement of \( \Delta \mu_{10} \) and Ponder’s Stark measurement\(^\text{33}\) is largely fortuitous given the error bars. Because the two-photon method can explicitly measure \( \Delta \mu_{10} \) for the lowest-lying \( 1B_u^{\#} \)-like state, removing all contributions from other participating states, we anticipate that the two-photon value (\( \Delta \mu_{10} = 13.5 \pm 0.8 \text{ D} \)) is the most accurate.

There is one aspect of Eq. (16) which may not be obvious upon first inspection, but which can have an interesting effect on both the magnitude as well as the frequency depen-

\(^a\) \((\gamma (\omega;0,0,0))\) in units of \(10^{-36}\) cm\(^3\) statCoulomb\(^{-2}\). All values in this table can be converted to SI units (F\(^3\) m\(^4\) C\(^{-2}\)) by multiplying by the conversion factor: \(1.238 \times 10^{-25}\) F\(^3\) m\(^4\) C\(^{-2}\) (cm\(^3\) statCoulomb\(^{-2}\)). Thus, in SI units, the Onsager (elliptical) \((\gamma (\omega;0,0,0))\) values are 1.34 \pm 0.63, 4.0 \pm 2.2 and 12.8 \pm 8.0 in units of \(10^{-36}\) F\(^3\) m\(^4\) C\(^{-2}\) at \(\omega = 1.833\), 1.916, and 1.959, respectively.

\(^b\) \((\gamma (\omega;0,0,0))\) based on Eq. (16) and a weighted nonlinear least-squares fit to the Onsager (elliptical) experimental results and the following parameters: \(\Delta \mu_{\omega l} = 12.8\) D, \(f_{\omega l} = 0.8\) (\(\mu_{\omega l} = 9.98\) D), \(\omega_{l} = 2.117\) eV, \(\omega_{0} = 0.031\) eV (250 cm\(^{-1}\)).

\(^c\) Time dependent Hartree–Fock methods based on the AM1, PM3, and MNDO Hamiltonians within MOPAC93 (see the text).

IV. COMMENTS AND CONCLUSIONS

We have examined the quadratic electrooptic effects (dc or low frequency Kerr effect) of bacteriorhodopsin dispersed in dried gelatin thin films. Data were collected at three wavelengths: 632.8 nm (He–Ne), 647.1 nm (Kr ion) and 676.4 nm (Kr ion). These wavelengths correspond to the near absorption edge region of the ground state of the bacteriorhodopsin (Fig. 1). The films show relatively large quadratic electrooptic effects compared to other molecular dispersed systems. The purple membrane is fixed within the polymerized gelatin matrix, and we show that the electronic contribution to \(\gamma\) dominates over possible orientational contributions. At 676 nm, the quadratic electrooptic coefficient \(s_{113}\) \((\omega;0.0,0)\) is \(6.7 \times 10^{-20}\) m\(^2\) V\(^{-2}\) and the third order nonlinear susceptibility

D. Comparison with theory

Time-dependent Hartree–Fock molecular orbital theory represents one of the more accurate methods available for calculating molecular hyperpolarizabilities. Kurtz and Koltzov have implemented versatile iterative procedures for calculating \(\alpha\), \(\beta\), and \(\gamma\) based on time-dependent methods within the MOPAC93 package. We used these methods to calculate \((\gamma (\omega;0,0,0))\) as a function of energy using for comparative purposes the AM1, PM3, and MNDO Hamiltonians. The iterative procedures are highly computationally intensive, particularly under resonance conditions. Despite the use of semiempirical Hamiltonians, we had to limit the calculation to the all-trans protonated Schiff base chromophore to achieve convergence at energies above 1.95 eV. The results are presented in the bottom three rows of Table IV.

The MNDO calculations do a relatively good job of reproducing the observed second-order hyperpolarizability considering the level of approximation and the fact that we are limiting the calculation to the chromophore. The fact that all three semiempirical parameterizations underestimate \((\gamma (\omega;0,0,0))\) may also be due to the inherent tendency of all three methods to underestimate dipole moment changes and inaccurately represent transition energies into the low-lying excited singlet states. We note that all calculations were carried out using the standard parameterization optimized for the ground state. Nevertheless, we consider the results from the MNDO calculations to be worth noting and suggest that this Hamiltonian is the best choice for calculating the hyperpolarizabilities of molecules using time-dependent Hartree–Fock methods with MOPAC.

FIG. 9. Schematic diagrams showing the molecular electronic origins of the type I, type II, and type III second-order hyperpolarizability enhancement processes. The symbol \(g(0)\) denotes the ground state of the all-trans protonated Schiff base chromophore and \(u(1)\) denotes the lowest-lying, strongly-allowed \(1B_g^+\)-like \(\pi,\pi^*\) state. The \(g(i)\) set of states includes all the higher energy \(1A_g^+\)-like \(\pi,\pi^*\) states with non-negligible transition moments with the lowest-lying \(1B_g^+\)-like state. Arrows between different states correspond to electronic transition moments. Arrows that return to the same state indicate electron reorganization resulting in dipole moment changes of that state relative to the ground state. The principal terms responsible for the enhancement based on the two-state (types I and III) and expanded multistate (type II) approximations are shown below the relevant diagrams.
\( \chi^{(3)}_{1133}(-\omega;0,0,0) \) is \( 7.0 \times 10^{-13} \text{ cm}^4 \text{ statCoulomb}^{-2} \), with both values obtained for a protein concentration of \( 6.9 \times 10^6 \text{ cm}^{-3} \). The value of \( s_{1133}(-\omega;0,0,0) \) varies linearly with protein concentration indicating that the protein, and only the protein, is responsible for the observed hyperpolarizability. The orientationally averaged second molecular hyperpolarizability \( \langle \gamma(-\omega;0,0,0) \rangle \) determined from the quadratic electro-optic coefficients at 676 nm assuming an Onsager ellipsoidal local field factor is \( (10.8 \pm 5.1) \times 10^{-32} \text{ cm}^7 \text{ statCoulomb}^{-2} \). The value of \( \langle \gamma(-\omega;0,0,0) \rangle \) increases tenfold to \( (103 \pm 65) \times 10^{-32} \text{ cm}^7 \text{ statCoulomb}^{-2} \), when the probe wavelength is decreased to 633 nm.

Quadratic electrooptic effects measured at 633 nm are enhanced at high incident light intensities. We suggest that this enhancement is due to the stationary state accumulation of the \( \text{O} \) intermediate of bacteriorhodopsin, which strongly absorbs the irradiation at 633 nm. We were able to compensate for this source of error by extrapolating the data back to low photon densities.

The \( \gamma(-\omega;0,0,0) \) values as a function of \( \omega \) were fit to a two-state model of the form

\[
\gamma(\omega;0,0,0) = \frac{\Delta \mu^2_{10} \times \mu^2_{10}}{\sqrt{(\omega_{10} - \omega)^3 + \omega_{D}^3}} + \frac{\mu^4_{10}}{\sqrt{\omega_{10}^6 (\omega_{10} - \omega)^4 + \omega_D^4}} + \text{cross terms},
\]

where \( \Delta \mu_{10} \) is the change in dipole moment, \( \mu_{10} \) is the transition moment, and \( \omega_{10} \) is the transition energy of the lowest-lying allowed \( ^1B_u \rightarrow \pi^* \) state. Our weighted nonlinear least squares fit indicates that \( \gamma(-\omega;0,0,0) \) is strongly enhanced via type III processes. That is, the magnitude of \( \gamma(-\omega;0,0,0) \) is dominated by the first term. We calculate that the dipole moment difference between the \( ^1B_u \rightarrow \pi^* \) state and the ground state is \( 12.8 \pm 1.2 \text{ D} \), in good agreement with the value determined from Stark measurements (12.4 D) and two-photon spectroscopy (13.5 \pm 0.8 D).

Time-dependent Hartree–Fock methods based on the MNDO Hamiltonian yield reasonable agreement with experiment, underestimating \( \gamma(-\omega;0,0,0) \) by factors of only 2–4, with the error increasing as the frequency approaches resonance. The AM1 and PM3 calculations were much less reliable, and thus we recommend use of the MNDO Hamiltonian for calculating hyperpolarizabilities within the MOPAC package.

**ACKNOWLEDGMENTS**

This work was supported in part by the National Institutes of Health (GM-34548). Specialized instrumentation was funded by the W. M. Keck Foundation. The authors thank Dr. Charles Martin and Igor Barani for their help with the theoretical calculations, and Bryan Vought and Constance Birge for help in preparing purified bacteriorhodopsin. We thank Jeff Stuart, Jack Tallent and Eric Tan for many helpful discussions.

**APPENDIX A: THE ELLIPSOIDAL LOCAL FIELD FACTORS**

The local field factor is defined as a ratio of an amplitude of the internal field \( E_i \) to that of the external field \( E_0 \).

The local field factor for a dipole placed in an ellipsoidal cavity was derived based on the theory of electric polarization described by Onsager and Böttcher.

We have two major effects to be considered to obtain an approximate field strength interacting with a dipole inside of the ellipsoidal cavity, namely, (1) The cavity field: \( E_c \), (2) Reaction field: \( R \). The internal field \( E_i \) should be a sum of the cavity field and the reaction field, that is,

\[
E_i = E_c + R.
\]

Additional field that arises from orientation of permanent dipoles and is called the directional field \( E_d \) should be considered if one works with liquid or gas phase. However, purple membrane is fixed in the gelatin matrix by the cross linked structure of the gelatin with hydrogen bonds, and the purple membrane is considered to be randomly oriented even under the external electric field. The effect from the directional field is therefore ignored here.

The cavity field for the ellipsoidal cavity is given by

\[
(E_c)_\alpha = \frac{\epsilon_2}{\epsilon_2 + (1 - \epsilon_2)A_\alpha} E_0, \quad \alpha \in \{a,b,c\}
\]

\( \epsilon_2 \) is dielectric constant of the matrix and \( A_\alpha \) is an ellipsoidal shape factor given by

\[
A_\alpha = \frac{abc}{2} \int_0^\infty \frac{ds}{(s + a^2)(s + b^2)(s + c^2)} = R_s, \quad \alpha \in \{a,b,c\},
\]

where \( a, b, \) and \( c \) are semimajor axes of the ellipsoidal cavity.

Meanwhile, the linear polarizability \( \alpha_s \), the reaction field factor \( f_a \) and the reaction field \( R_a \) in the \( a \) direction are given as

\[
\alpha_a = \frac{(\epsilon_1 - 1)}{3[1 + (\epsilon_1 - 1)A_a]} \frac{abc}{A_a(1 - A_a)(\epsilon_2 - 1)}
\]

\[
f_a = \frac{\epsilon_2}{\epsilon_2 + (1 - \epsilon_2)A_a}
\]

\[
R_a = \frac{f_a \alpha_a}{1 - f_a \alpha_a} E_c
\]

Assuming the direction of the external field \( E_0 \) is along the semimajor axis of the ellipsoid, \( a \), substitution of (A4) into (A1) yields

\[
E_i = \frac{1}{1 - f_a \alpha_a} E_c = \frac{\epsilon_2}{\epsilon_2 + (1 - \epsilon_2)A_a} E_0
\]

From (A5), the local field factor at a static field for the ellipsoidal cavity is obtained as

\[
\frac{E_i}{E_0} = \frac{1}{1 - f_a \alpha_a} = \frac{\epsilon_2}{\epsilon_2 + (1 - \epsilon_2)A_a}
\]
by letting \( \epsilon_1 \) be a permittivity at an optical frequency \( \epsilon_1(\omega) \) and \( \epsilon_2 \) a permittivity at static field \( \epsilon_2(0) \). For a field at an optical frequency, by assigning \( \epsilon_1 \) and \( \epsilon_2 \) to represent permittivities at optical frequencies \( \epsilon_1(\omega) \) and \( \epsilon_2(\omega) \), respectively, we obtain

\[
 f_{\text{ell}}^{(0)} = \frac{\epsilon_2(0)\{1 + (\epsilon_1(\omega) - 1)A_2\}}{\epsilon_2(\omega) + (\epsilon_1(\omega) - \epsilon_2(\omega))A_2}. 
\]

(A6)

For a spherical cavity, \( A_2 = 1/3 \). In such a case (A6) is reduced to

\[
 f_{\text{spher}}^{(0)} = \frac{\epsilon_2(0)(\epsilon_1(\omega) + 2)}{2\epsilon_2(\omega) + \epsilon_1(\omega)}. 
\]

(A8)

which is identical to the Onsager's local field factor for a spherical cavity. Similarly for the ellipsoidal local field factor at optical frequency, a spherical local field factor at an optical frequency is obtained from (A7)

\[
 f_{\text{spher}}^{(0)} = \frac{\epsilon_2(\omega)(\epsilon_1(\omega) + 2)}{2\epsilon_2(\omega) + \epsilon_1(\omega)}. 
\]

(A9)

In a more simple physical picture than the Onsager's model, where the reaction field is not taken into account, the local field can be written as sum of an external field and a polarization field inside an ellipsoidal cavity or a spherical cavity. The extent to which the polarization \( P_2 \) affects the internal field is given by the depolarizing tensor \( \mathbf{L} \)

\[
 \mathbf{E}_i = \mathbf{E}_0 + 4\pi \mathbf{L} \cdot \mathbf{P}_2. 
\]

(A10)

Substituting \( P_2 = (\epsilon_2 - 1)\mathbf{E}_0/4\pi \), where \( \epsilon_2 \) is a permittivity of the dielectric, into (A10) and rearrangement yields

\[
 \mathbf{E}_i = [I + (\epsilon_2 - 1)\mathbf{A}] \cdot \mathbf{E}_0. 
\]

(A11)

The diagonal components of \( \mathbf{L} \), \( L_{ii} \), are equal to \( A_\alpha \) when the shapes of the molecule and the cavity are ellipsoidal. Consequently, the internal field is given by

\[
 \mathbf{E}_i = [I + (\epsilon_2 - 1)\mathbf{A}] \cdot \mathbf{E}_0. 
\]

(A12)

Because \( \mathbf{A} \) is a diagonal tensor,

\[
 E_i = [1 + (\epsilon_2 - 1)A_\alpha]E_\alpha, 
\]

\[
 \alpha \in \{a, b, c\}. 
\]

(A13)

Assuming the direction of the external field \( \mathbf{E}_0 \) is along the semimajor axis of the ellipsoid, \( a \), the Lorentz-type local field factor for the ellipsoidal cavity is thereby defined as

\[
 f_{\text{ell}}^{(0)} = 1 + (\epsilon_2(\omega) - 1)A_\alpha. 
\]

(A14)

For a spherical cavity, \( A_2 = 1/3 \). Then (A14) is reduced to

\[
 f_{\text{spher}}^{(0)} = \frac{\epsilon_2(\omega) + 2}{3}. 
\]

(A15)

\( f_{\text{ell}}^{(0)} \) or \( f_{\text{spher}}^{(0)} \) are also defined for the Lorentz-type local field factors similarly to those defined for the Onsager type local field factors

\[
 f_{\text{ell}}^{(0)} = 1 + (\epsilon_2(\omega) - 1)A_\alpha, 
\]

(A16)

\[
 f_{\text{spher}}^{(0)} = \frac{\epsilon_2(\omega) + 2}{3}. 
\]

(A17)

### APPENDIX B: RELATION BETWEEN \( \chi^{(3)}(\omega;0,0,\omega) \) AND \( \gamma(\omega;0,0,\omega) \)

A third order macroscopic polarization at an optical frequency \( \omega \) is given by

\[
 P^{(3)}_i = \chi^{(3)}_{ijkl}E^{(0)}_j E^{(0)}_k E^{(0)}_l 
\]

(B1)

while a microscopic polarizability for each molecule at an optical frequency \( \omega \) is given by

\[
 P^{(3)}_i = \gamma_{ijkl}E^{(0)}_j E^{(0)}_k E^{(0)}_l 
\]

(B2)

Here, \((i,j,k,l,\ldots)\) denotes indices for film coordinates while \((i',j',k',l',\ldots)\) denotes indices for molecular coordinates for each molecule. This quantity corresponds to an induced dipole moment of a molecule. \( E^{(0)}_\text{local} \) is a local field corrected electric field and related to external field as

\[
 (E^{(0)}_{\text{local}})_i = (f^{(0)}_{\text{ell}} E^{(0)}_{\text{ell}})_i. 
\]

(B3)

The third order polarization can be related to the microscopic polarizability with the local field factors

\[
 P^{(3)}_i = \sum_{x=1}^{N} R^x_{ii'} \gamma_{ijkl} E^{(0)}_j E^{(0)}_k E^{(0)}_l 
\]

(B4)

Similarly, relation between the macroscopic susceptibility \( \chi^{(3)} \) and the microscopic susceptibility \( \gamma \) is

\[
 \chi^{(3)}_{ijkl} = \sum_{x=1}^{N} R^x_{ii'} \gamma_{ijkl} E^{(0)}_j E^{(0)}_k E^{(0)}_l 
\]

\[
 \times \gamma_{j'l'k'l'}(\omega;0,0,\omega) f^{(0)}_{j'l'} f^{(0)}_{j'} f^{(0)}_{l'l'} f^{(0)}_{l'.} 
\]

(B5)

\( R^x_{ii'} \) is a tensor that converts a molecular coordinate of \( x \)th molecule \( i' \) to a coordinate \( i \) fixed in the film. For simplicity, we will calculate an orientational average of the microscopic susceptibility \( \gamma \) and try to relate it to the macroscopic susceptibility \( \chi^{(3)} \).

The orientational average of \( \gamma \) can be obtained by examining the symmetry of permutations of the applied fields for the expression of \( \gamma(\omega;0,0,\omega) \) given by Orr and Ward\(^{44} \) and by taking known nonzero components of \( \gamma \) for the point group of the molecule (C\(_i \) in this case) into account. By neglecting the damping terms, their expression can be reduced in the near resonance or resonance region to

\[
 \gamma_{j'l'k'l'}(\omega;0,0,\omega) f^{(0)}_{j'l'} f^{(0)}_{j'} f^{(0)}_{l'l'} f^{(0)}_{l'.} = 4K(\omega;0,0,\omega) f^{(0)}_{j'l'} f^{(0)}_{j'} f^{(0)}_{l'l'} f^{(0)}_{l'.} 
\]

\[
 \times \sum_{lmn\neq g} \left[ \frac{\langle g | \mu_{j'l'} | l \rangle \langle l | \mu_{j'} | m \rangle \langle m | \mu_{j} | n \rangle \langle n | \mu_{j'} | g \rangle}{(\omega_{mg} - \omega_{g})(\omega_{mg} - \omega_{g})} \right] 
\]

\[
 - \sum_{lmn\neq g} \left[ \frac{\langle g | \mu_{j'} | m \rangle \langle m | \mu_{j'} | g \rangle \langle g | \mu_{j} | n \rangle \langle n | \mu_{j'} | g \rangle}{(\omega_{mg} - \omega_{g})(\omega_{mg} - \omega_{g})} \right] 
\]

(B6)
where \( I \) denotes the average of all terms generated by permuting \( -\omega_{\alpha}, \omega_{\beta}, \omega_{\gamma}, \) and \( \omega_{3} \) and \( K \) is a numerical factor with labels in (B6) and whose value depends on the presence of zero frequencies and repeated frequency in the set \( \omega_{\alpha}, \omega_{\beta}, \omega_{\gamma}, \) and \( \mu_{ij} \) is a ground state dipole moment of the chromophore along \( i' \) direction in the molecular coordinate. \( |n\rangle \) and \( |g\rangle \) denote state vectors for a \( n \)th state and a ground state of the chromophore, respectively.

By noting that: (1) two of the four frequencies in Eq. (B6) are equal, i.e., either 0 or \( \omega \), (2) Eq. (B6) allows exchange between the indices \( i' \) and \( j' \) and between \( k' \) and \( l' \) (3) all components are nonzero for \( C_{1} \) symmetry, one obtains the orientationally averaged value of \( \gamma \) for a tensor component measured in the state of the chromophore, respectively.

\[
\langle \gamma_{ij}^{t} | \langle t' | (\omega; 0, 0, 0) \rangle_{ijkl} = \frac{1}{I} \left( \gamma_{xx} + \gamma_{yy} + \gamma_{zz} \right) + \frac{1}{I} \left( \gamma_{xy} + \gamma_{yx} + \gamma_{zx} + \gamma_{xz} \right) + \frac{1}{I} \left( \gamma_{yz} + \gamma_{zy} \right) + \gamma_{zz}
\]

(B7)

Using (B7), (B5) can be rewritten for isotropic medium as

\[
\left\langle \chi_{ij}^{(3)} (\omega; 0, 0, 0) \right\rangle = \frac{1}{N \gamma_{ij}^{0} f_{\text{ellipse}}^{(0)} f_{\text{ellipse}}^{(0)} f_{\text{ellipse}}^{(0)}} \left( \gamma (\omega; 0, 0, 0) \right)_{ijkl} \cdot (B9)
\]

Here denotes an average value over the molecular coordinates \( x, y, z \) and experimentally measured value as a tensor component specified with the indices for the molecular coordinate \( i, j, k, l \). Because the linear field factors are constants at specific frequency, the linear relationship between \( \chi_{ij}^{(3)} \) and \( \gamma \) found in (B9) is assured by the observation of a linear relationship between \( s_{1133} \) and concentration (Fig. 5).

35. M. C. Ponder, Ph.D., University of California, Berkeley, 1983.
