Abstract

Beaver dam analogues (BDAs) are a stream restoration technique that is rapidly gaining popularity in the western United States. These low-cost stream-spanning structures, designed after natural beaver dams, are being installed to confer the ecologic, hydrologic and geomorphic benefits of beaver dams in streams that are too degraded to provide suitable beaver habitat. BDAs can slow streamflow, reduce the erosive power of the stream and promote aggradation, making them attractive restoration tools in incised channels. Despite increasing enthusiasm for BDAs, few studies to date have evaluated the impacts of these structures on channel morphology. Here, we examine the geomorphic changes that occurred within the first year of restoration efforts in south-central Wyoming using high-resolution visible light orthophotos and elevation data collected with unoccupied aerial vehicles (UAVs). By leveraging the advantages of rapidly acquired images captured by low-cost UAV surveys with recent advancements in Structure from Motion photogrammetry, we constructed centimeter-scale digital elevation models (DEMs) of the restoration reach and an upstream reference reach. Through DEM differencing, we identified areas of enhanced erosion and deposition around the BDAs, suggesting that BDA installation initiated a unique geomorphic response beyond the scale of natural channel variability. However, we measured net erosion in both reaches which is counter to the desired restoration outcome of net aggradation around the BDAs. This net loss of sediment is inconsistent with studies of natural beaver dams, underscoring the differences between BDAs and the dams that inspired their construction, but is in agreement with theoretical channel evolution models of beaver-related stream restoration. To better understand the impacts of BDAs on channel morphology and restoration efforts throughout the Mountain West, it is imperative

that we consistently assess the effects of beaver-inspired restoration projects across a range of hydrologic and geomorphic settings and that we continue this monitoring for years to decades.

**EVALUATING THE GEOMORPHIC CHANNEL RESPONSE TO BEAVER DAM
ANALOGUE INSTALLATION USING UNOCCUPIED AERIAL VEHICLES**

I am incredibly grateful to my mentors and colleagues at Syracuse University and beyond. Thank you to the faculty, students and staff in the Earth and Environmental Sciences Department at Syracuse University for encouraging my development as a scientist and for providing me with the opportunities and support that led to this thesis. Thank you to my colleagues in the Lautz research group for your feedback and suggestions over the last two years. I would particularly like to thank Nathaniel Chien for collecting the 2017 data and getting this project off the ground, J.R. Slosson for his thoughtful comments on my manuscript and Julio Beltran for his unwavering positivity and strong work ethic during the second field season. In addition, I thank Ruta Basijokaite for her constant encouragement and for the coffee breaks that fueled much of the data analysis in this thesis.

Thank you to the Central New York Association of Professional Geologists, the Syracuse University Earth and Environmental Sciences Department and the Education Model Program on Water-Energy Research (No. DGE-1449617) for financially supporting this project. I would also like to acknowledge support from the National Science Foundation Graduate Research Fellowship (Grant No. 1650114). Thank you to Andrea Turnbull for organizing and disbursing these awards and to Annie Pennella for reviewing my many seed grant proposals and for being a constant source of encouragement. I would also like to thank the founding and current principal investigators of EMPOWER, Dr. Laura Lautz and Dr. Charles Driscoll, for conceiving of and ensuring the success of this program.

This work would not be possible without our collaborators at The Nature Conservancy of Wyoming, particularly John Coffman, Dr. Courtney Larson and Dr. Corinna Riginos. Thank you for inviting us to partner with you on this project, providing access to the research site and

assisting with field work. I appreciate everything you have taught me about Red Canyon Ranch, the social and political context of beaver-inspired restoration, and the importance of effective communication across organizations and disciplines. In addition, I would like to thank Chris Kratt and Chris Sladek from the Air Center for Transformative Environmental Monitoring Programs for their timely and effective provision of experimental design support, logistical support and equipment for the project (NSF EAR awards 1440596 and 1440506).

I am extremely grateful to the beaver dam analogue research team. Thank you to Dr. Chris Russoniello for teaching me different field methods and for helping me grow as a research scientist. Thank you to my committee member Dr. Philippe Vidon for his research guidance and for keeping the team's spirit strong during long days in the field. Thank you to my committee member Dr. Christa Kelleher for fostering and sharing my excitement for UAVs, for her insight during the research process and for encouraging me to pursue multiple funding and professional development opportunities. I would especially like to thank my advisor, Dr. Laura Lautz. Thank you for the opportunity to be part of this incredible team, for encouraging me to invest in all aspects of my development as a scientist and for your thoughtful mentorship. In addition, I would like to thank Casey Pearce for her unwavering support, for sharing this experience with me and for being there during all the highs and lows of the research process.

A final word of appreciation goes to my family and friends for their encouragement and love. A special thank you to Aaron Davis for always believing in me, cheering me on and sharing my passion. Few people would be excited about building a beaver dam analogue in the pond behind the house or spending two days of our vacation doing fieldwork and I am grateful that you are one of those people.

1. Introduction

Channel incision is a widespread phenomenon that is causing ecosystem degradation in streams and adjacent riparian areas throughout the western United States (e.g. Chaney, Elmore and Platts, 1990; Pollock, Beechie and Jordan, 2007; Beechie, Pollock and Baker, 2008; Polvi and Wohl, 2013; Pollock et al., 2014; Livers et al., 2018). While it is difficult to identify a single driver of this incision in most hydrologic systems, climate change and human activity have been linked with accelerated downcutting and stream deterioration. In arid and semi-arid regions of the western United States, natural erosive processes induced by strong precipitation events and high topographic relief are exacerbated by shifts in the intensity and frequency of precipitation, the timing of peak spring streamflow and recent human alteration of stream channels and floodplains (Naiman, Johnston and Kelley, 1988; Chaney et al., 1990; Pollock et al., 2007; Beechie et al., 2008; Polvi and Wohl, 2013; Livers et al., 2018). Changes in land use, particularly hydromodification and water diversion (e.g. Pollock et al., 2007; Burchsted, Daniels, Thorson and Vokoun, 2010), the conversion of productive bottomlands to agricultural fields (e.g. Wohl, 2005), overgrazing in riparian corridors (e.g. Apple, 1985; Chaney et al., 1990; Trimble and Mendel, 1995) and the decline in beaver populations due to habitat loss and trapping (Naiman et al., 1988; Pollock, Heim and Werner, 2003; Pollock et al., 2007; Polvi and Wohl, 2013) have further diminished channel stability.

Degradation resulting from these natural and anthropogenic disturbances leads to channel confinement. As the streambed erodes and streamflow is constricted between steep, nearly vertical banks, base level decreases. Streams become physically and hydrologically severed from elevated floodplains and the local water table drops. These hydrologic responses limit surface water-groundwater exchange and cause riparian vegetation to senesce, reducing plant density and diversity (e.g. Apple, 1985; Krueper, 1993). Although riparian zones cover < 1% of land area,

they are extremely productive and provide critical forage, habitat, and surface water access in otherwise dry regions, making these narrow vegetated corridors a key focus of restoration efforts in the western United States (Apple, 1985; Chaney et al., 1990; Krueper, 1993; Bouwes et al., 2016).

Given the hydrologic and ecologic impacts of channel incision, the goal of many stream restoration projects in degraded systems is to counter the erosive processes dominating in the channel. By minimizing erosion and promoting aggradation, restoration efforts seek to raise the streambed and reconnect the stream and floodplain (e.g. Palmer et al., 2005; Pollock et al., 2007; Beechie et al., 2010; Curran and Cannatelli, 2014; Pollock et al., 2014). Strategies to reshape stream geometry range from invasive and expensive to more passive and low-cost approaches. As interest in natural channel design and process-based restoration has increased, dramatic restoration efforts such as channel fill and relocation have given way to smaller scale projects using engineered rock weirs, cross-vanes and check dams (Rosgen, 2001; Wilcox, Benoit and Mink, 2001; Fanelli and Lautz, 2008; Beechie et al., 2010; Rosgen, 2013; Norman et al., 2017). More passive, ecologically-focused approaches seek to initiate restoration by replanting vegetation near the stream to improve bank stability, by adding large woody debris to create more complex streamflow patterns and by encouraging beaver reintroduction and dam building to dissipate flow energy (Apple, 1985; Wohl, 2015; Bouwes et al., 2016).

As beaver populations have recovered in the western United States, land owners, land managers and researchers have noted the hydrologic, geomorphic and ecologic benefits of beaver dams (Apple, 1985; Naiman et al., 1988; Butler and Malanson, 1995; Meentemeyer and Butler, 1999; Pollock et al., 2007; 2014). However, beaver translocation and reintroduction are not feasible in all settings. Beaver-human conflict, such as nuisance beaver activity, limit the areas

where beavers can be successfully introduced (Pollock et al., 2014; Dittbrenner et al., 2018; Pilliod et al., 2018). In addition, some systems are too degraded to support beavers, particularly those that are deeply incised or lack adequate vegetation for dam construction and food (Pollock et al., 2014; Dittbrenner et al., 2018; Lautz et al., 2019). In systems such as these, beaver-inspired restoration efforts such as beaver dam analogues (BDAs) are quickly gaining popularity (Pollock et al., 2014; Pilliod et al., 2018; Lautz et al., 2019; Shahverdian et al., 2019; Scamardo and Wohl, 2020).

BDAs are stream-spanning structures that are constructed from natural materials and are intended to mimic natural beaver dams in both form and function (Pollock et al., 2014; 2017; Pilliod et al., 2018; Shahverdian et al., 2019). BDAs are semi-permeable and are designed to be dynamic, short-term restoration tools (Lautz et al., 2019). Typically, BDAs are built by pounding wooden fence posts vertically into the streambed, weaving willow or other vegetation through the posts and stabilizing the dam with gravel and streambed sediments (Pollock et al., 2017; Shahverdian et al., 2019) but construction varies based on geomorphic settings, local vegetation and project budgets. Like natural beaver dams, BDAs can create upstream impoundments, elevate stream water and local groundwater levels, reduce flow velocities and induce deposition of suspended sediments, all of which contribute to restoring connectivity between the stream and floodplain (Apple, 1985; Naiman et al., 1988; Meentemeyer and Butler, 1999; Westbrook, Cooper and Baker, 2006; Pollock et al., 2007; 2014). The widespread adoption of BDAs throughout the western United States is likely a result of their simple design and construction using primarily natural materials, making them a relatively inexpensive restoration strategy (Pollock et al., 2017; Pilliod et al., 2018; Shahverdian et al., 2019).

Despite the inferred similarities between beaver dams and BDAs, there is uncertainty about whether they can create the same morphologic changes especially in degraded systems (Pollock et al., 2014; Lautz et al., 2019). Although BDAs are intended to deliver the benefits of natural beaver dams in the absence of beavers, the two structures have unique construction, lifespans, maintenance frequency and geomorphic settings. Beavers continuously repair and rebuild their dams, which can last decades (Butler, 1995), while BDAs generally receive annual maintenance and have design lifespans of just a few years (Johnson et al., 2019; Lautz et al., 2019). BDAs can be installed in incised channels that offer only marginal beaver habitat due to concentrated flow energy, steep banks and limited riparian vegetation (Pollock et al., 2014; Dittbrenner et al., 2018; Pilliod et al., 2018; Lautz et al., 2019). Additionally, most studies on the morphologic impacts of beaver dams span decades, enabling assessments of the long-term impacts of beaver dams on the landscape (e.g. Meentemeyer and Butler, 1999; Westbrook, Cooper and Baker, 2011; Levine and Meyer, 2014). In contrast, BDAs are a relatively new restoration technique and most projects are still in the early stages. Altogether, there is a dearth of information and peer-reviewed studies to date on the impacts of BDA installation despite strong interest from land managers and the increasing popularity of beaver-inspired stream restoration (Majerova et al., 2015; Bouwes et al., 2016; Pilliod et al., 2018; Silverman et al., 2018; Vanderhoof and Burt, 2018; Weber et al., 2018; Scamardo and Wohl, 2020).

BDAs are intended to be installed in sequence, similar to natural beaver dam construction, with the entire BDA complex spanning hundreds of meters to a few kilometers along a stream (Pollock et al., 2014; Bouwes et al., 2016; Vanderhoof and Burt, 2018; Scamardo and Wohl, 2020). Therefore, analyzing the geomorphic impacts of these restoration structures necessitates matching the scale of measurement with the scale of the restoration project such that

geomorphic changes can be resolved at individual BDAs as well as along a kilometer-scale reach. At fine scales, field-based methods such as erosion pins and topographic field surveys provide detailed point measurements at the expense of time and spatial density (Lawler, 1993; Pollock et al., 2007; Curran and Cannatelli, 2014). At coarser scales, airborne light detection and ranging (LiDAR) surveys generate spatially continuous, decimeter-scale topographic data along several kilometers of a stream but these surveys are cost prohibitive for many projects (e.g. Brasington, Vericat and Rychkov, 2012; Cook, 2017). In contrast and as a complement to these other approaches, unoccupied aerial vehicles (UAVs) can be deployed quickly and are a user friendly, low cost platform for acquiring visible light (red-green-blue, RGB) images of a restoration area. The RGB images can be used to generate both orthophotos and topographic data when combined with Structure from Motion (SfM) photogrammetric software (e.g. Westoby, Brasington, Glasser, Hambrey and Reynolds, 2012; Fonstad, Dietrich, Courville, Jensen and Carbonneau, 2013). SfM-generated topographic data have accuracies comparable to airborne LiDAR and topographic field surveys while offering flexibility in the temporal and spatial scales of observation (e.g. Fonstad et al., 2013; Cook, 2017). UAV- and SfM-based geomorphic analyses have been performed to estimate erosion in agricultural drainages (Prosdocimi, Caligaro, Sofia, Dalla Fontana and Tarolli, 2015) and after intense flooding events (Tamminga, Eaton and Hugenholtz, 2015; Cook, 2017). Though many studies have affirmed the accuracy of UAV- and SfM-derived measurements of fluvial processes (e.g. Prosdocimi et al., 2015; Tamminga et al., 2015; Hamshaw et al., 2017; Marteau, Vericat, Gibbins, Batalla and Green, 2017), there are fewer examples of UAV and SfM application in analyzing geomorphic changes resulting from stream restoration efforts (e.g. Carrivick and Smith, 2018; Duró, Crosato, Kleinhans and Uijttewaal, 2018).

In this study, we examine the morphologic response to a BDA restoration project in Red Canyon Creek, Wyoming, to understand the impacts of BDA installation on channel form and fluvial processes. Using data from annual UAV surveys, we assess the geomorphic changes that occurred during the first year after BDAs were installed in an incised channel. By comparing the morphologic response near the BDAs with geomorphic changes in an upstream reference reach, we constrain the impacts of the BDAs from natural channel variability to better understand the geomorphic outcomes of beaver-inspired restoration efforts. As the literature on BDAs is limited and few field studies have considered the impacts of BDAs on channel morphology (e.g. Scamardo and Wohl, 2020), our work provides some of the first benchmarking of geomorphic adjustments in response to BDA installation. We also consider the advantages and limitations of using UAVs and SfM to measure channel response to restoration efforts. As BDAs continue to gain popularity, developing a thorough understanding of their potential benefits and limitations is necessary to inform future beaver-inspired restoration efforts.

2. Methods

2.1 Study Area

Red Canyon Creek is a meandering third-order stream in south-central Wyoming, on the eastern flank of the Wind River Range (Figure 1). The 84 km² watershed is largely coincident with Red Canyon Ranch, an active cattle ranch owned and sustainably managed by The Nature Conservancy (TNC) of Wyoming (Lautz, Siegel and Bauer, 2006). Red Canyon Creek flows south to north through Red Canyon Ranch and is fed by two tributaries, Barret Creek and Cherry Creek, before discharging into the Little Popo Agie River. In this semi-arid region, peak streamflow occurs during snowmelt in the late spring and early summer (Lautz et al., 2006).

Stream substrate and alluvial floodplain sediments are predominantly sandy gravel and silt and are sourced from the Triassic Chugwater Formation, an iron-rich sandstone and siltstone that underlies the eastern half of the watershed (Lautz et al., 2006; Fanelli and Lautz, 2008). The streambed is incised approximately 1.5 m to 3 m below the floodplain.

TNC has encouraged beaver activity in the watershed and local beaver populations have intermittently occupied reaches of Red Canyon Creek (Lautz et al., 2006), although today isolated beaver colonies inhabit only the upper tributaries in the watershed. Beavers last occupied the lower reaches of Red Canyon Creek in 2015. The recent loss of beavers and their dams, coupled with above average precipitation and streamflow events since 2015, has exacerbated legacy incision and further disconnected the stream from the riparian floodplain.

To counter this degradation, TNC installed five beaver dam analogues (BDAs) along a ~250 m reach of Red Canyon Creek in 2018 (Figure 1c) with the goals of slowing streamflow, particularly during spring peak flows, and promoting aggradation on the streambed to begin reconnecting the stream and floodplain. The first BDA (BDA 2) was built in April 2018 and the remaining four were installed in August 2018 during a field workshop on BDA restoration practices hosted by TNC, Utah State University and the Natural Resources Conservation Service. The BDAs were built using a variety of construction approaches, with the central three BDAs (BDAs 2–4) constructed following the prototypical post and willow design and placed approximately 30 m apart. BDA 1 was constructed using a post-less adaptation of the typical BDA design and BDA 5 was built without gravel or sediments. The two distal BDAs were destroyed within one year of installation.

The stream segments analyzed in this study are located in an approximately 500 m reach of Red Canyon Creek downstream of the confluence with Cherry Creek (Figure 1b–c). In this

lower reach, the stream gradient is less than 2% (Lautz et al., 2006) and the channel is incised about 1 to 2 m below the adjacent riparian floodplain. The experimental BDA reach spans approximately 100 m of the stream and includes the central BDA complex (BDAs 2, 3 and 4). Since BDAs 1 and 5 were destroyed before the 2019 UAV survey, they are excluded from the BDA reach. A portion of Red Canyon Creek approximately 150 m upstream of the BDA installation sites was selected as the reference reach. The reference reach is approximately 130 m in length. Like the BDA reach, it flows transversely across the floodplain and has a sinuosity of 1.6, similar to the BDA reach sinuosity of 1.5. Due to the distance between the two reaches, any potential influence of restoration activity on the reference reach is minimized.

2.2 Unoccupied Aerial Vehicle (UAV) Surveys

Annual unoccupied aerial vehicle (UAV) surveys were conducted from 2017 to 2019 to capture the geomorphic changes related to BDA installation (Table 1). The first survey occurred one year prior to BDA installation (August 2017), the second survey was completed less than a week after BDA installation (August 2018) and the third survey was approximately one year following BDA installation (July 2019). Flights were contracted with the Air Center for Transformative Environmental Monitoring Programs (CTEMPs) from Oregon State University and the University of Nevada, Reno. Air CTEMps generated the flight plans and executed the UAV surveys. In each flight, forward image overlap and image sidelap were at least 70% to ensure repeat coverage of the entire study area and to allow for the creation of precise, high-resolution digital elevation models (DEMs). In 2017 and 2018, geotagged nadir visible light images were collected using a Sony A5100 onboard a DJI Phantom 4. In 2019, images were captured with a Sony R10 mounted on a DJI M600. All flight details are summarized in Table 1.

Prior to each survey, we placed 10 to 13 targets throughout the study area to serve as ground control points (GCPs) for positional registering during subsequent photogrammetry. In 2017, we used 0.3 m (1 ft) white bucket lids marked with black electrical tape as GCPs. In 2018 and 2019, we constructed the GCPs from 0.3 m (1 ft) black and white checkered floor tiles fastened to 1.8 m (6 ft) lengths of white tarp to increase the visibility of the GCPs in UAV images. We measured the coordinates of each GCP relative to a local benchmark using a Nikon Nivo 5.M total station, which has horizontal (northing and easting) accuracy and precision of 2 cm and vertical (elevation) accuracy and precision of 0.6 cm.

2.3 Image Processing and DEM Creation

The UAV images were processed in Agisoft PhotoScan Pro version 1.3.4 using the same settings throughout the workflow for each year (Agisoft, 2017). Where applicable, we present the settings we used at each processing step. After the images were uploaded the software computed image quality, a parameter based on image sharpness that ranges from zero (blurred) to one (very sharp). We discarded images with sharpness values less than 0.7 (compared to a recommended threshold of 0.5; Agisoft, 2017), applying a more conservative threshold so that only the clearest images were retained. Across the three years, we removed only seven images (all from 2019) due to poor image quality caused by blur and glare.

PhotoScan then aligned the images by automatically detecting the same feature in at least two overlapping images. To specify the criteria for aligning images, we assigned a key point limit of 40,000 and a tie point limit of 4,000. Based on these settings, PhotoScan identified 40,000 unique features in each image based on attributes such as brightness and color (Fonstad et al., 2013). Of those 40,000 points, 10% were retained as tie points. The 4,000 tie points were

used to calculate internal and external camera orientations and parameters as well as to perform a scale invariant feature transform, generating a sparse 3D point cloud with spatial positioning determined from the 2D geotagged images (James and Robson, 2012; Westoby et al., 2012; Fonstad et al., 2013). We refined the spatial accuracy of the sparse point cloud by visually identifying each GCP in at least two images and marking GCP centers with the surveyed coordinates. The resulting registered point cloud was projected into the WGS 84 / UTM Zone 12N (EPSG::32612) coordinate system.

Using the sparse point cloud, we performed a gradual selection process to remove tie points with high errors or uncertainties and to optimize camera calibration parameters. We removed tie points generated from fewer than three images, with reconstruction uncertainties less than 10 pixels, with reprojection errors less than 0.5 pixels or with projection accuracies less than 10 cm. During this iterative process, we deleted approximately 80% of the tie points. PhotoScan then generated a final dense point cloud from the remaining tie points using a mild depth filter and medium quality. The mild depth filter retained fine-scale details in the point cloud and preserved data continuity and the medium quality setting reduced computation time by subsampling images by a factor of four. The resulting dense point clouds contained between ~27 million and 78 million points and were used to produce digital elevation models (DEMs) with resolutions from 3.5 cm pixel⁻¹ to 6.9 cm pixel⁻¹ (Table 1). DEMs and high resolution orthophotos were then exported to ArcMap 10.7 for further analysis.

2.4 DEM Error Analysis

As an independent measure of DEM accuracy, we conducted a detailed topographic field survey in 2019 coincident with the UAV flight. Using a Nikon Nivo 5.M total station, we

measured the locations of 24 static well casings on the floodplain and 165 submerged points upstream and downstream of BDAs 2–4 to serve as check points, as well as water surface elevations around each BDA. We compared the elevations of the check points with DEM-derived elevations to calculate error metrics (mean error, root mean square error, standard deviation of error, maximum absolute error) for both dry and wet areas. For dry areas, we compared elevations only where the well casings were clearly visible in the orthophotos to minimize the influence of vegetation on DEM-reported elevations. Errors were calculated by subtracting field-measured elevations from DEM-generated elevations. Negative errors indicate that the DEM underpredicts elevations and positive errors indicate that the DEM elevations are higher than surveyed elevations.

Given that there are known issues with estimating elevations in submerged areas, we tested a refraction correction on the 2019 DEM with our highly resolved survey observations ($n = 165$). The correction is based on the index of refraction at the air-water interface and is applied to account for the systematic overestimation of submerged topography in SfM-generated DEMs (e.g. Westaway, Lane and Hicks, 2000; 2001; Woodget, Carbonneau, Visser and Maddock, 2015). Other corrections use pixel RGB or brightness values and are based on changes in water color with increasing depth (e.g. Westaway, Lane and Hicks, 2003; Tamminga, Hugenholtz, Eaton and Lapointe, 2014; Strick et al., 2019) but due to a change in camera and image colors between 2018 and 2019 (Table 1), we did not test a color-based correction. To estimate true streambed elevations, we calculated water depths based on the 2019 DEM and multiplied the depths by the refractive index of water ($n = 1.34$), then subtracted the difference between the corrected and uncorrected water depths from the DEM.

2.5 DEM Differencing and Change Detection

The DEMs were resampled to the coarsest resolution (6.9 cm pixel⁻¹) and aligned to ensure direct pixel-to-pixel comparisons. To highlight areas of geomorphic change after BDA installation, we compared the 2018 and 2019 DEMs using Geomorphic Change Detection 7.0 (GCD) software (<http://gcd.joewheaton.org>) in ArcMap 10.7 (Wheaton, Brasington, Darby and Sear, 2010). GCD calculated elevation changes between the successive DEMs to create DEMs of difference (DoDs) for the BDA reach and the reference reach. By measuring the areal extent of elevation changes in each reach, the GCD software estimated volumes of erosion and deposition between 2018 and 2019. To minimize the impacts of vegetation and shadows on calculated elevation changes, we restricted the analyses to areas of the study reaches where the channel was visible in both years.

To distinguish true geomorphic changes from DEM error, we tested three uncertainty thresholds commonly used in similar analyses: raw (unthresholded), a simple minimum level of detection (minLoD ; Brasington, Rumsby and McVey, 2000) and probabilistic thresholding at a 95% confidence interval (Wheaton et al., 2010). Elevation changes below the uncertainty thresholds could not be confidently distinguished from noise in the DoDs and were discarded. We calculated the minLoD by propagating the error in each DEM into the DoD (e.g. Brasington, Langham and Rumsby, 2003; Lane, Westaway and Hicks, 2003), using

$$\varepsilon DoD = \sqrt{(\varepsilon DEM_{new})^2 + (\varepsilon DEM_{old})^2} \quad (1)$$

where εDoD is the propagated DoD error and εDEM_{new} and εDEM_{old} are the errors calculated for each DEM. To calculate the 95% confidence interval (CI) threshold, we multiplied the minLoD by the student's t-value for the chosen confidence interval ($t = 1.96$ for the 95% CI).

Using each uncertainty threshold, the GCD software calculated the spatial extents and volumes of geomorphic changes.

3. Results

3.1 DEM Accuracy Assessment

As this study analyzes morphologic changes after BDA installation, we focus on the 2018 and 2019 DEMs in the following text. The root mean square errors (RMSEs) calculated by PhotoScan during point cloud creation and registration were generally consistent with the accuracy of the total station used to survey the GCPs and orient the point cloud with real-world coordinates (Table 1). In 2018 and 2019, the horizontal RMSEs calculated by PhotoScan and used as a measure of accuracy ranged from 0.74 cm to 1.53 cm. These accuracies were lower than the 2 cm accuracy of the total station which suggested that the modeled point clouds had good spatial alignment with the surveyed real-world coordinates. The RMSEs were higher in 2019, at 1.53 cm and 1.42 cm for easting and northing, respectively, but were consistent with total station accuracy and lower than the final DEM resolution of 6.9 cm pixel⁻¹. Based on the agreement between the low horizontal RMSEs and instrument accuracy, we are confident in the positional accuracies of the resulting DEMs.

The elevation RMSE was below the total station accuracy of 0.6 cm in 2019 but reached 1.02 cm in 2018 (Table 1). The higher residual in 2018 suggested poorer agreement between surveyed and modeled elevations after point cloud transformation and alignment. To further examine this offset, we compared the DEM elevations with the surveyed elevations at the check points on the floodplain (see Section 2.4 DEM Error Analysis). The RMSE and standard deviation of the error (SDE), used as measurements of accuracy and precision, respectively, were

higher in 2018 (RMSE = 11.8 cm and SDE = 8.9 cm) than in 2019 (RMSE = 4.7 cm and SDE = 3.7 cm; Table 2), consistent with the annual error metrics calculated by PhotoScan (Table 1). Five check points were excluded from the error calculations in 2018 (Table 2) due to vegetation obscuring the well casings in the orthophoto. All error metrics were positive despite negative elevation differences at some check points, showing that the DEM-reported elevations could be higher or lower than the surveyed elevations (Figure 2a). The error statistics we calculated are consistent with other UAV-based studies of fluvial geomorphology (e.g. Tamminga et al., 2015; Cook, 2017; Marteau et al., 2017) and therefore are appropriate for DEM differencing.

For submerged portions of the channel, the refraction correction improved the accuracy of DEM-derived bathymetry. After the correction, the mean error (ME) and RMSE decreased from 36.4 cm to 27.3 cm and from 42 cm to 36.3 cm, respectively (Figure 2b and Table 2). However, the uncorrected data had a higher precision with the SDE increasing from 20.9 cm to 24 cm after the correction. As the refraction correction did not consistently improve the elevation measurements in submerged areas, we used the original uncorrected data in our analyses. We acknowledge that the reported streambed elevations overestimated true stream bathymetry and incorporate this offset into our calculations of geomorphic change.

Following Brasington et al. (2003) and Wheaton et al. (2010), we calculated the different uncertainty thresholds using the SDE as the estimate of elevation error. Using Equation (1), we calculated a minLoD of 9.8 cm. The probabilistic threshold was more restrictive, only retaining elevation changes that were above a desired confidence interval. We calculated the 95% CI level of detection by multiplying the minLoD by the corresponding t-value for the 95% CI ($t = 1.96$), resulting in a 19.2 cm level of detection.

3.2 Planform Changes in Channel Morphology

The BDAs initiated a morphologic response in the stream that resulted in areas of both deposition and erosion (Figure 3). From 2018 to 2019, deposition occurred upstream of BDAs 2 and 3 with lateral accretion concentrated on the insides of the meanders (Figure 3g–h). Much of this deposition was on areas that were visibly vegetated in 2017 and 2018 (Figure 3a–b, 3d–e and 3g–h). Downstream of BDAs 3 and 4, erosion was the dominant morphologic change with >1 m of cut bank retreat immediately downstream of each BDA (Figure 3h–i). We note that the visible changes from 2017 to 2018 are restricted to changes in channel inundation due to water level adjustments in response to BDA installation versus actual changes in channel morphology (Figure 3a–f).

3.3 Geomorphic Changes from DEM Differencing

The elevation changes quantified in the DoDs are consistent with the planform changes visible in the orthomosaic images with deposition upstream of BDAs 2 and 3 and erosion downstream of BDAs 3 and 4 (Figures 3–5). The same spatial patterns are apparent regardless of the uncertainty threshold applied, with smaller magnitude changes being discarded as the level of detection becomes more restrictive (Figures 5–6 and Table 3). The greatest vertical elevation change in the BDA reach occurred upstream of BDA 2 where up to 0.8 m of sediment were deposited (Figure 5). BDAs 3 and 4 also trapped sediment, but that deposition was limited in spatial extent and magnitude compared to the point bar aggradation upstream of BDA 2. The most intense erosion was concentrated downstream of BDAs 3 and 4, where elevations decreased by up to 2 m as a result of bank slumping and retreat from 2018 to 2019. The DoDs also revealed subtle elevation changes such as deposition between BDAs 3 and 4, erosion upstream of BDA 3

and minor decreases in elevation immediately downstream of BDAs 2 and 3 associated with scour pool formation. Despite differences in the magnitudes of measured elevation changes around each BDA, all three dams exhibited a consistent pattern where some detectable deposition occurred upstream and erosion occurred downstream (Figure 5).

Although the range of elevation changes in the reference reach was larger than in the BDA reach, the majority of these changes were small in magnitude (± 20 cm) and below the thresholds for the minLoD (9.8 cm) and the 95% CI (19.2 cm; Figure 6). When the minLoD was applied, there were detectable changes across 43% of the 433 m^2 reference reach area and 66% of the 415 m^2 BDA reach area (Figure 5 and Table 3). With the 95% CI, these percentages decreased to 20% and 36% of reference and BDA reach areas, respectively.

Regardless of the threshold applied, both reaches had a net loss of sediment from 2018 to 2019 (Table 3). Using more restrictive thresholds increased the net sediment loss per stream length. For example, the normalized net volumetric change in the BDA reach increased from 0.16 m^3 of sediment lost per meter of stream when no threshold was applied to 0.21 $\text{m}^3 \text{m}^{-1}$ for the 95% CI. The different uncertainty thresholds had a more dramatic impact on net volume calculations in the reference reach, where net sediment loss was 0.04 m^3 per meter of stream when measured from the raw DoD and 0.15 $\text{m}^3 \text{m}^{-1}$ when measured from the 95% CI DoD. This bias towards greater erosion as the threshold becomes more restrictive is a function of the vertical elevation changes resulting from erosion and deposition. Across both reaches, positive elevation changes exhibited a smaller range than negative elevation changes; therefore, net volumes calculated from more restrictive thresholds favored erosion (Figure 6 and Table 3).

Although there was net sediment export from both reaches, the geomorphic changes in the BDA reach impacted a greater area and resulted in more sediment movement than the

changes in the reference reach. Although the range of elevation changes was greater in the reference reach, with a maximum vertical elevation change of 1.06 m and a minimum of -3.06 m, the areas over which detectable elevation changes occurred were larger in the BDA reach resulting in higher calculations of erosion and deposition (Figure 6 and Table 3). Overall, the gross volumes of erosion and deposition in the BDA reach were approximately 1.5–2 times greater than the gross volumes in the reference reach. For example, at the 95% CI there were $0.25 \text{ m}^3 \text{ m}^{-1}$ of deposition and $0.46 \text{ m}^3 \text{ m}^{-1}$ of erosion in the BDA reach but in the reference reach, there were only $0.1 \text{ m}^3 \text{ m}^{-1}$ of deposition and $0.25 \text{ m}^3 \text{ m}^{-1}$ of erosion (Table 3).

At the 95% CI, geomorphic changes in inundated portions of the BDA reach were largely excluded (Figure 5e). Since the level of detection at the 95% CI (19.2 cm) is similar to the DEM error in submerged areas (20.9 cm; Table 2), the detected elevation changes retained in the DoD at the 95% CI were likely areas of true erosion and deposition and not a result of DEM noise. The general patterns of geomorphic change within and between the two reaches were not altered when submerged portions of the channel were incorporated or excluded (Figures 5–6 and Table 3). Therefore, we judge the most conservative threshold to be appropriate for this study and rely on calculations from the 95% CI in subsequent analyses, although we report volumetric changes at the other two thresholds as well (Table 3).

Four cross sections over the DEMs highlight localized changes in the channel, informing the nature of vertical erosion and deposition and providing 2D examples of the morphologic differences we observed in the DoDs (Figure 7). From 2018 to 2019, the channel became more asymmetric upstream of each BDA (Figure 7 A–A', B–B' and C–C'). Point bar deposition upstream of BDA 2 constricted the channel width to approximately 3.2 m, narrower than the active channel width in 2017 or 2018 (Figures 3 and 7 A–A'). Deposition upstream of BDA 2

increased the streambed elevation across much of the submerged channel with the exclusion of localized scour along the left bank (Figure 7 A-A'). Similarly, deposition upstream of BDA 4 occurred on the exposed left bank and on the streambed, locally raising streambed elevation before a transition to channel scour at the right bank (Figure 7 C-C'). Upstream of BDA 3, the channel also narrowed and became more asymmetric after BDA installation with erosion concentrated on the outside of the meander and deposition along the inner meander (Figures 3, 5 and 7 B-B'). The most extreme erosion occurred downstream of BDA 4, with >2 m of lateral cut bank retreat and ~1.7 m of vertical erosion (Figures 3, 5 and 7 D-D').

The cross sections also illustrate the effects of vegetation and water depth on DEM-reported elevations. Changes in vegetation height manifest in increases and decreases in elevation but can be distinguished from bare-earth elevation changes through inspection of the annual orthophotos (Figures 3, 4b and 7). The increases in elevation near the right bank in the 2019 cross sections aligned with transitions from exposed sediment to grass (Figure 7). From 2018 to 2019, the increases in elevation at the right bank at B-B', C-C' and D-D' were attributed to vegetation growth (Figures 3e-f, 3h-i and 7). Decreases in elevation near the center of the channel in A-A' and B-B' were the result of vegetation being submerged and buried after BDA construction (Figures 3 and 7). These plants were visible immediately upstream of BDAs 2 and 3 in the 2018 orthophotos but were largely absent in the 2019 orthophotos (Figure 3d-e and 3g-h). Comparing the bathymetry reported by the 2019 DEM with the surveyed streambed points illustrates the discrepancy between field-measured and DEM-reported elevations (see Sections 2.4 DEM Error Analysis and 3.1 DEM Accuracy Assessment). In submerged areas, the survey elevations were consistently lower than the DEM-generated elevations and this offset increased with water depth (Figure 7). In D-D', turbulence downstream of BDA 4 exacerbated

the DEM over-prediction of streambed elevations illustrating the sensitivity of UAV-generated topographic data to poor water clarity. Fortunately, the 95% CI we established excluded areas of turbulence downstream of each BDA from the DoD and subsequent volume calculations (Figures 3g–i and 5e).

4. Discussion

4.1 Do BDAs Initiate a Unique Morphologic Response?

In all three uncertainty scenarios, the same pattern of geomorphic change persisted: we observed greater erosion and deposition around the BDA complex than in the upstream reference reach (Figures 5–6 and Table 3). Gross deposition in the BDA reach was $0.15 \text{ m}^3 \text{ m}^{-1}$ greater than in the reference reach (Table 3). The difference in gross erosion between the two reaches was even more pronounced at $0.21 \text{ m}^3 \text{ m}^{-1}$. These differences suggest that the BDAs initiated a morphologic response in the channel that both exceeded the magnitude of natural channel variability and was unique from the morphologic responses to physical drivers such as precipitation, valley slope and suspended sediment load. As the two reaches in this study are ~150 m apart and are both oriented transversely across the floodplain, we assume that the physical drivers impacting the two reaches are comparable. Although we used a high 95% CI threshold that discarded elevation changes over the majority of the reach areas, this restrictive level of detection exchanged a loss of information for an improvement in the geomorphic plausibility of the measured elevation changes (Wheaton et al., 2010).

Combining orthophotos, high resolution DEMs and field observations enabled us to detect how patterns of erosion and deposition were influenced by the evolution of the BDAs and their interaction with the surrounding landscape. The pattern of deposition and erosion around

individual BDAs manifests at the reach scale as well, with deposition concentrated upstream of the BDA complex and erosion dominating downstream of the BDA complex. The majority of the deposition in the BDA reach occurred upstream of BDA 2 with some additional deposition upstream of and between BDAs 3 and 4 (Figures 3 and 5e). The distribution of erosive changes along the reach mirrors deposition, with minor erosion downstream of BDA 2 and cut bank retreat downstream of BDAs 3 and 4. This transition from deposition dominating upstream to erosion dominating downstream is in contrast to the reference reach where the morphologic changes were more spatially random with no clear differentiation between elevation changes in the upstream or downstream areas (Figure 5f). There are several possible explanations for this pattern, including (1) BDA order, (2) vegetation presence and (3) BDA breaches.

Although BDAs are semi-permeable, they do impound water and can generate head drops of at least 15 cm showing that they effectively slow streamflow (Table 4). As the first standing BDA in the complex, BDA 2 dissipated stream energy and created an upstream area of slower streamflow that enabled the deposition of suspended sediment. Downstream of BDA 2, there was likely a lower suspended sediment load, reducing the potential for deposition at subsequent BDAs. BDA 2 may have also trapped sediment that was mobilized when BDA 1 failed in addition to vegetative remnants of that dam. Near BDAs 2 and 3, deposition occurred preferentially along the right bank and narrowed the active channel width (Figures 3 and 5). These areas of higher deposition are along the inner edges of meanders and were vegetated in 2018, two physical factors that likely contributed to the enhanced local deposition.

Notably, each BDA breached along the left bank, either by overtopping flow or scour along the streambed (Figure 8). At BDA 2, flow beneath the dam caused an area of visible turbulence downstream (Figures 3g and 8a). Some of this erosion is captured by the DoD

although it is less pronounced than the erosion at BDAs 3 or 4 (Figure 5e). BDA 3 breached along the left bank, resulting in streamflow overtopping and flowing around the dam and higher turbulence downstream (Figures 3h and 8b). The small channel avulsion near BDA 3 created an area of unobstructed streamflow and directed erosive energy against the left bank which retreated by >1 m between 2018 and 2019 (Figure 5e). The most intense erosion occurred downstream of BDA 4, likely the result of a large breach in the dam that preferentially directed streamflow against the left bank (Figures 3i, 5e and 8c). Despite this breach, BDA 4 maintained an upstream impoundment and corresponded to the largest drop in head, a 45 cm decrease in water surface elevation over the dam (Table 4).

The cut bank retreat downstream of BDAs 3 and 4 resulted in 1 to 2 m of vertical elevation decreases that, although limited in area, were responsible for the enhanced erosion in the BDA reach compared to the reference reach (Figure 5e, Figure 6 and Table 3). The bimodal distribution of volumetric elevation changes in the BDA reach suggests that these higher magnitude changes contributed to approximately 50% of the erosion that occurred from 2018 to 2019. These breach-driven morphologic changes highlight the importance of installing BDAs in sequence as downstream BDAs can capture some of the sediment lost due to breaches upstream and retain material within the reach. The contribution of BDA breaches to the geomorphic changes we measured also underscores the benefit of coupling on-the-ground observations with multiple remote sensing measurements. We readily identified the breaches and the associated areas of erosion in the field but due to breach-generated turbulence some of the observed morphologic changes, notably scour ponds downstream of each BDA, were poorly captured by the UAV-derived topography (Figures 5 and 7).

The concentration of deposition-induced morphologic changes at the upstream BDA and the transition to erosion dominating at downstream BDAs suggest that BDA order and breaching strongly influence potential aggradation. However, a 2020 study on sedimentation upstream of BDAs in Colorado found BDA height to be the most significant variable in models predicting sediment accumulation (Scamardo and Wohl, 2020). Interestingly, at the Colorado field sites the tallest BDA was the most downstream structure where pond sedimentation was measured. However, Scamardo and Wohl (2020) did not report any BDA breaches which suggests that BDA construction and breaching may impact patterns of erosion and deposition. In addition, differences in methodology and the time elapsed between measurements may contribute to the unique channel responses we identified. Scamardo and Wohl (2020) compared field measurements of sediment accumulation in upstream ponds over two to three months in summer and fall whereas our findings emphasize morphologic changes along the streambanks and span nearly one year.

4.2 Can BDAs Achieve Restoration Goals?

Beaver-inspired restoration in incised channels is aimed at increasing sedimentation and channel aggradation (Pollock et al., 2007; 2014; Scamardo and Wohl, 2020). While the morphologic response measured in the BDA reach of Red Canyon Creek is counter to this restoration goal, there are several explanations for our particular finding that BDAs generate net erosion. First, there was net sediment loss in both study reaches suggesting that net erosion would have occurred in the experimental reach regardless of BDA presence. The pattern of net erosion in both reaches suggests that physical drivers of channel form, such as precipitation, elevated the erosive power of the stream from 2018 to 2019. Unusually high precipitation in May

and June 2019 resulted in higher than average streamflow, inundating the BDAs. BDA 5 failed during this heavy precipitation period, as determined from field photos provided by TNC, likely due to the high erosive energy in the stream. It is possible that this period of intense precipitation is responsible for the breaches observed in the standing BDAs and much of the downstream cut bank retreat as well. However, without comprehensive field observations or UAV surveys bracketing this period of extreme precipitation, we cannot determine the exact contribution of this unusual weather event to changes in channel form.

Second, our study spans the initial year of restoration activity during which the stream was dynamically responding to the addition of the BDAs. As the system adjusts and establishes a new equilibrium state, a transition from erosion-dominated morphologic changes to net deposition may be possible. Multi-year studies of natural beaver dams have found that net deposition occurs several years after dam construction although the aggradation rate is highly variable and often attributed to factors other than dam age and construction, such as climate, lithology and slope (e.g. Butler and Malanson, 1995; Westbrook et al., 2011; Levine and Meyer, 2014). The range of sedimentation rates measured in beaver ponds across the continental United States spans from centimeters to >1 m per year (e.g. Naiman et al., 1988; Butler and Malanson, 1995; Pollock et al., 2007; Westbrook et al., 2011). In the Mountain West, typical sedimentation rates upstream of beaver ponds range from 1–20 cm year⁻¹ when measured over a 6 year timespan (Westbrook et al., 2011) and from 2–28 cm year⁻¹ for dams between 3 and 30 years in age (Butler and Malanson, 1995). If we assume these sedimentation rates represent the maximum deposition possible in the ponds upstream of BDAs in Red Canyon Creek, the uncertainty threshold we used for change detection (95% CI = 19.2 cm) would have rendered much of that potential deposition in submerged areas undetectable. As BDAs and beaver dams are distinct

structures with different construction and maintenance it may not be realistic to assume that they would result in similar deposition rates (Lautz et al., 2019). BDAs are typically more permeable than beaver dams which suggests that BDAs may be less effective in creating ponded regions of slower streamflow and in trapping sediment upstream (Scamardo and Wohl, 2020). In addition, active beaver dams are constantly maintained and repaired but recommended BDA maintenance is on an annual timescale (Pollock et al., 2017), allowing for the possibility of enhanced erosion due to breaching as we observed downstream of BDAs 3 and 4. The breaches and downstream bank retreat we identified are consistent with findings of net erosion associated with abandoned beaver dams or dam-induced overbank flooding during high flow events (e.g. Burchsted and Daniels, 2014; Curran and Cannatelli, 2014; Levine and Meyer, 2014).

While this study is one of first to analyze the geomorphic changes resulting from a beaver-inspired stream restoration project, channel evolution models have been used for decades to understand and predict a linear transition from degraded channels to restored systems at new equilibrium states (e.g. Schumm, Harvey and Watson, 1984; Simon and Hupp, 1986; Thorne, 1999). More recently, these models have been updated to include a range of initial morphologic conditions, incorporate the cyclical nature of channel incision and aggradation (Cluer and Thorne, 2014) and consider ecological processes and biotic agents such as beavers (Pollock et al., 2014). In a four-stage channel succession model that cycles between incision, trench widening, aggradation and dynamic equilibrium, beaver reintroduction has the most potential to arrest incision and initiate aggradation during the second phase, trench widening (Pollock et al., 2014). Where streams are too incised for beavers to inhabit, the addition of debris dams or BDAs may offer some of the same benefits as natural beaver dams (e.g. Pollock et al., 2007; 2014; Lautz et al., 2019). In the context of a beaver-mediated channel evolution model, the trench

widening phase, during which erosion is the dominant physical process, is a critical part of restoration. As flow is rerouted due to BDA installation and possible dam breaching, bank erosion increases the active channel width. In a wider channel the erosive power of the stream is reduced and a transition towards net aggradation can begin, initiated in part by downstream BDAs trapping sediment that eroded further upstream. If breaches in existing BDAs are repaired and new BDAs are installed, this transition from net degradation to net aggradation can be sustained. The duration of each phase in channel succession is highly variable but can last for decades. Beaver reintroduction or BDA installation has the potential to accelerate the transition from trench widening to aggradation but this process will still likely take several years depending on the extent of degradation and the sediment supply in the stream (Pollock et al., 2014).

In an incised channel such as Red Canyon Creek, the detection of appreciable deposition is unlikely just one year after BDA installation given theoretical channel evolution models and the uncertainty in the methods we used. It is important to note, however, that the only other study focused on geomorphic changes near BDAs found that the dams successfully trapped sediment and initiated deposition (Scamardo and Wohl, 2020). This discrepancy highlights the need for continued monitoring of these restoration sites as BDAs have been shown to accumulate increasing sediment volumes as they age (Bouwes et al., 2016) and also highlights the possible influences of measurement method and restoration site characteristics such as incision depth, channel slope, lithology and climate on desired outcomes. However, the lack of net aggradation over the course of this study does not suggest that the BDAs in Red Canyon Creek will fail to meet restoration objectives. Rather, BDA installation may have initiated a transition from an actively incising system to a channel widening system, increasing the potential for net aggradation over the next few years. The breaches we observed are not a failure of the BDA

design but instead are consistent with the theoretical BDA-mediated restoration cycle and the one-year expected lifespan of BDAs (Pollock et al., 2014).

4.3 Are UAVs a Viable Tool for Assessing Geomorphic Changes in Fluvial Systems?

RGB images captured during UAV surveys are a powerful tool, providing both elevation data and continuous visible light orthophotos of study areas that allow for visual assessment of morphologic changes, detailed mapping of geology and vegetation cover and quantification of geomorphic processes (e.g. Cook, 2017; Duró et al., 2018). As such, UAVs are gaining popularity in studies of morphologic change and SfM-derived topographic data are being used to measure processes ranging from moraine formation in Iceland (Chandler et al., 2020) and soil deflation in Greenland (Heindel, Chipman, Dietrich and Virginia, 2018) to bank erosion in agricultural drainages (Prosdocimi et al., 2015) and geomorphic changes following large flooding events (Tamminga et al., 2015; Cook, 2017). In fluvial settings, UAVs have been used to measure the morphology of bedrock gorges in Taiwan (Cook, 2017), anthropogenically straightened rivers in the Netherlands (Duró et al., 2018) and sandy braided rivers in Canada (Strick et al., 2019).

The accuracy of UAV- and SfM-generated topographic data has been evaluated through comparisons with terrestrial laser scanning (TLS), airborne LiDAR and topographic field surveys. In exposed and well-illuminated areas, UAV data rival the accuracy of these more expensive or time consuming data collection methods (e.g. Prosdocimi et al., 2015; Tamminga et al., 2015; Cook, 2017; Hamshaw et al., 2017; Strick et al., 2019). However, in submerged areas the accuracy of optical remote sensing declines with increasing water depth (Figure 7; Westaway et al., 2000; 2001). While multiple corrections have been developed to improve the accuracy of

elevation data in inundated areas, these corrections perform best when the streambed and wetted edge of the stream are clearly visible (Westaway et al., 2000, 2001, 2003; Tamminga et al., 2014; Woodget et al., 2015; Dietrich, 2017). Overhanging vegetation, shadowed streambanks, sun glint on the water surface, turbulence or high turbidity drastically reduce the accuracy of these corrections (e.g. Cook, 2017; Dietrich, 2017). The apparent failure of the refraction correction we applied to the 2019 DEM is likely due to a combination of these factors, including vegetation obscuring the water surface and stream edge (Figure 4a), shadows resulting from steep streambanks and near-stream vegetation (Figure 4c), ripples and turbulence downstream of the BDAs (Figure 3g–i), sun glint and floating debris, all of which reduced streambed visibility in the UAV data. Combining a more robust method for measuring submerged topography, such as total station surveys, multibeam echo sounders (Javernick, Brasington and Caruso, 2014) or bathymetric LiDAR (e.g. Bailly, Le Coarer, Languille, Stigermark and Allouis, 2010; Kinzel, Legleiter and Nelson, 2013), with UAV-derived elevation data for exposed surfaces is an alternative to our approach of using a more restrictive threshold to account for elevation uncertainty in wetted portions of the channel. However, merging different data acquisition methods obviates the key advantages of UAV data, namely the high spatial resolution, efficiency and low cost. Regardless, when ideal UAV flight conditions cannot be met due to weather, turbidity or limited field access, we recommend complimenting UAV surveys with another method to measure streambed topography. Using the current study as an example, robust measurements of channel form across the streambed would have allowed us to use a lower uncertainty threshold, retain more elevation data and resolve morphologic changes in the BDA ponds with higher confidence.

The exclusion of vegetated areas where the UAV data likely reports elevations somewhere between the ground surface and canopy height (Cook, 2017) has little impact on our findings. The BDAs were installed in an incised channel and did not raise water levels to the floodplain elevation so any morphologic changes beyond the active channel are irrelevant to our assessment of geomorphic responses to BDA installation. However, the presence of vegetation on the floodplain likely impacted our assessment of DEM error. We attribute the lower error metrics in 2019 in part to the enhanced visibility of the well casings in the UAV data. Prior to the 2019 topographic survey and UAV flight, we cleared the vegetation surrounding the well casings but we did not clear those areas in previous years. Despite the exclusion of obscured check points in 2018, the impact of vegetation height is apparent in the elevation differences calculated between the DEM and total station survey data (Figure 2a). The plateau in elevation differences around ~0.2 m is consistent with the 2018 DEM incorporating partial vegetation heights into the final elevation model.

The nadir perspective of traditional UAV flights prevents the SfM elevation data from reliably reconstructing the shape of eroded streambanks, particularly where undercutting or scour has occurred. Eroded banks appear vertical and any small-scale topographic variations are lost (Figure 7 D–D'). Incorporating oblique camera perspectives can improve bank reconstruction either by using a flexible multi-rotor UAV platform or by adding ground based photos to the SfM workflow (e.g. Prosdocimi et al., 2015; Hamshaw et al., 2017; James, Robson, d'Oleire-Oltmanns and Neithammer, 2017; Duró et al., 2018). Field measurements using erosion pins capture morphologic changes along concave banks but these point measurements can be challenging to integrate with remote sensing data and cover limited portions of the channel.

Given these challenges and advantages of UAVs for assessing morphologic changes, we consider them to be one of many viable tools. UAV- and SfM-generated data have the unique benefit of providing both reach-scale orthophotos and detailed elevation measurements from a single RGB camera. By comparing the coregistered orthophotos and DEMs, we were able to distinguish true geomorphic changes from areas of vegetation growth and focus our analyses on unobscured portions of the channel. The continuity of UAV data allowed us to identify spatial trends, such as the repeated pattern of upstream deposition and downstream erosion at each BDA, which may have been lost in point measurements from erosion pins or topographic field surveys. When SfM data are used in concert with another data type, such as terrestrial laser scanning, aerial or bathymetric LiDAR or a detailed topographic field survey, submerged regions can be better resolved, a comprehensive accuracy assessment can be performed and higher confidence levels can be assigned to areas where the different datasets agree. In this study, we rely on areas where there is stronger agreement between the UAV data and field elevation data to drive our conclusions. In these portions of the channel the geomorphic changes measured exceed the magnitude of DEM uncertainty, allowing decimeter-scale changes to be resolved with high confidence.

5. Conclusion

In apparent contrast to the aggradation desired from BDA restoration projects, we found an increase in erosion around a complex of three BDAs. However, when placed in the context of the larger watershed and of channel evolution models, these results are not surprising. There was net sediment loss in an upstream reference reach as well, suggesting that the physical drivers acting on the system over the one year timeframe of the study favored erosion. Compared to the morphologic changes in the reference reach, the channel response to BDA installation resulted in

volumes of erosion and deposition that were nearly double those measured in the reference reach, supporting the idea that BDAs initiate unique geomorphic responses beyond those that can be attributed to natural channel variability. We found that BDA position in the sequence and dam integrity influenced the patterns of geomorphic change, with deposition concentrated upstream of the first BDA and dam breaches due to overtopping streamflow resulting in cut bank retreat at downstream BDAs. Although a breach formed in each standing BDA and two of the original five dams were completely destroyed within one year, these findings are consistent with the dynamic and temporary design of BDAs and underscore the importance of installing these structures in sequences, similarly to how beavers construct their dams, so that the impacts of a few BDAs failing can be absorbed by the remaining intact structures.

The short lifespan of BDAs demands methodological approaches for assessing the impacts of these structures on fluvial systems that can be rapidly deployed and have flexible spatial and temporal resolutions. The coincident evolution of Structure from Motion (SfM) photogrammetry and development of low-cost, lightweight UAV platforms have enabled the collection of elevation data at scales capable of resolving morphologic changes with centimeter-scale accuracy. Although the combination of UAVs and SfM has been successfully applied in a few studies of channel erosion, these methods have not been widely adopted for monitoring stream restoration. We demonstrate several advantages of UAV- and SfM-generated data, notably the benefit of simultaneously acquiring both visible light orthophotos and elevation data and the ability to repeatedly assess how the stream system responds to restoration efforts. Given the discrepancy between the strong enthusiasm for BDAs and the dearth of data assessing the effectiveness of these beaver-inspired structures, there is an immediate need for additional

monitoring across restoration sites and over longer time frames to better understand the potential outcomes of BDA restoration efforts.

Figures

Figure 1. (a) The beaver dam analogues were installed at Red Canyon Ranch in south-central Wyoming. (b) The main stream flowing through the ranch is Red Canyon Creek, a third-order stream that flows to the north. The study area is located near the northern terminus of the stream. Digital elevation model (10 m pixel^{-1}), watershed extent and stream locations are from the U.S. Geological Survey (U.S. Geological Survey, 2017; 2019). (c) Five beaver dam analogues (red) were installed in Red Canyon Creek in 2018. BDAs 2–4 were intact in July 2019 and are the focus of this study (‘BDA Reach’). An upstream reach with a similar gradient and sinuosity was selected as a reference (‘Reference Reach’).

Figure 2. Density plots comparing DEM elevations with elevations from a 2019 topographic survey for (a) exposed and (b) submerged points. Elevation differences were calculated by subtracting field elevations from DEM elevations. Dashed lines show the mean error values calculated between the two elevation datasets (Table 2). (b) The corrected submerged data was adjusted following Woodget et al. (2015).

Figure 3. Annual orthophotos (2017–2019) of the installation sites for BDAs 2–4. A camera change between the 2018 and 2019 UAV surveys is responsible for the color changes (Table 1). Streamflow is from left to right. Arrows indicate the locations of the BDAs.

Figure 4. Differencing the (left) 2019 DEM and (center) 2018 DEM results in the (right) DEM of difference (DoD). Positive elevation changes indicate an increase in elevation from 2018 and 2019 and negative elevation changes indicate a decrease in elevation. Black lines indicate the locations of the BDAs. The elevation changes in the DoD result from true geomorphologic changes in the channel, (a) variations in shadow presence between 2018 and 2019, (b) changes in vegetation height on the floodplain and (c) the influence of vegetation obscuring the active channel.

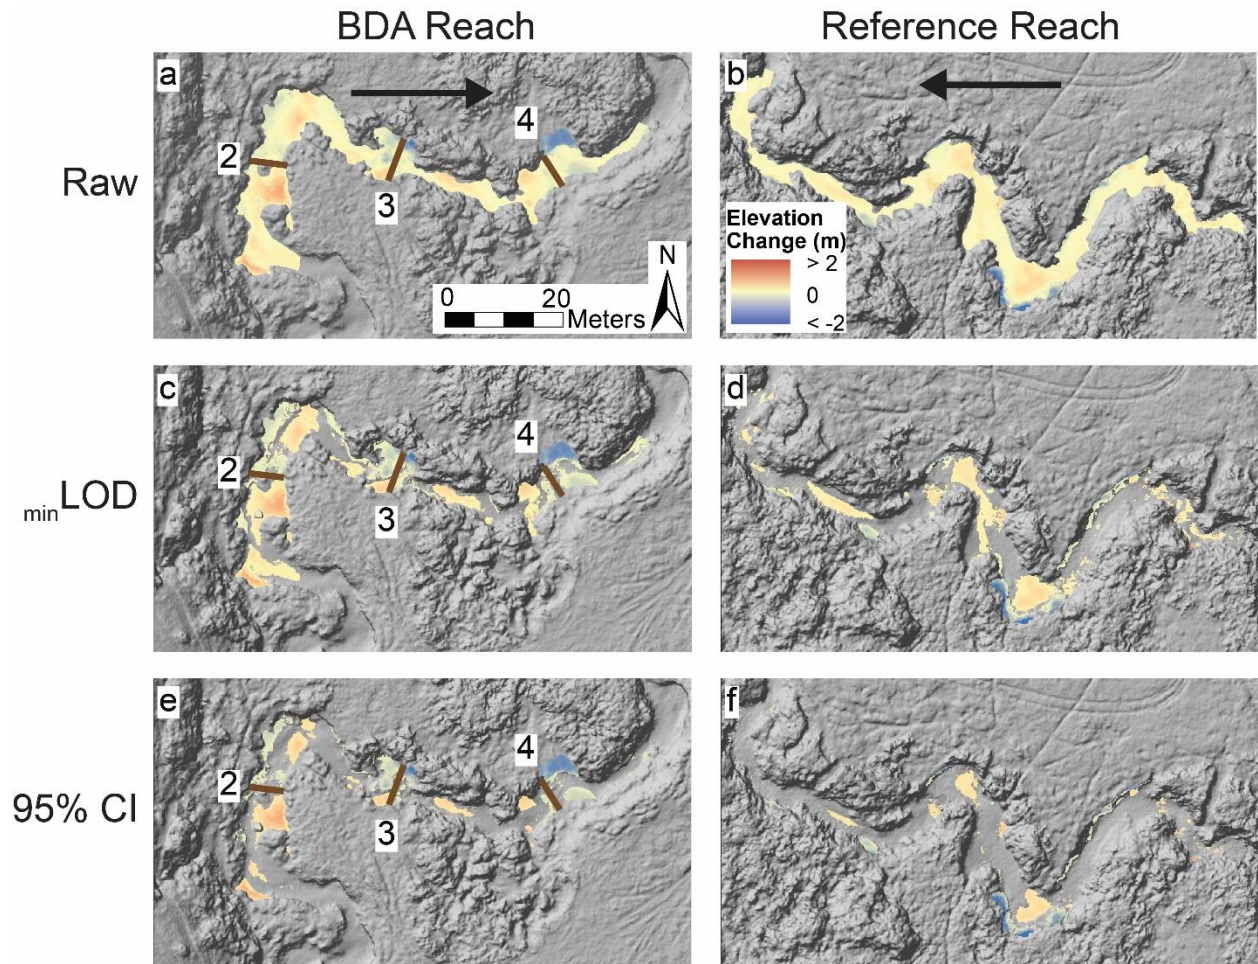

Figure 5. 2018–2019 DEM of difference (DoD) restricted to the two study reaches. Three error assessments are shown: a raw, unthresholded DoD (a–b), a 9.8 cm minimum level of detection threshold ($_{\min}\text{LoD}$; c–d) and a 19.2 cm 95% confidence interval threshold (95% CI; e–f). Brown lines indicate the locations of the BDAs. Black arrows indicate flow direction. The DoDs are overlain on the 2018 hillshade model.

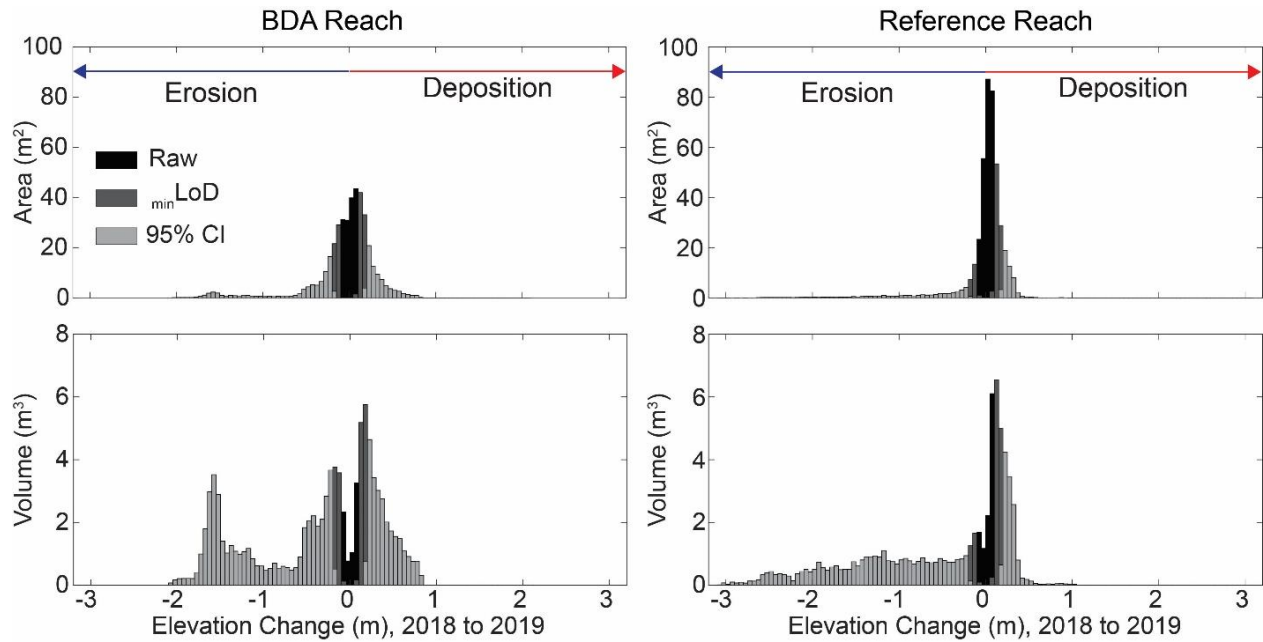

Figure 6. Areal and volumetric elevation change distributions for the BDA reach and the reference reach. Elevation changes were calculated by subtracting 2018 elevations from 2019 elevations and are shown using 5 cm binning. Light grey bars are data above the 95% confidence interval (95% CI). Dark grey bars show the additional data included when the uncertainty threshold is reduced to the minimum level of detection ($_{\min}\text{LoD}$). Black bars are the data excluded by both uncertainty thresholds.

Figure 7. Cross sections over the 2018 and 2019 digital elevation models (DEMs). Dashed lines indicate DEM-reported elevations below the water surface. Green ‘Vs’ indicate areas of elevation change resulting from variations in vegetation presence and height. The black ‘T’ indicates a portion of the 2019 DEM where turbulence interfered with DEM-reported elevations. Note the different X and Y axes for each cross section.

Figure 8. Field photos showing the breaches at each BDA. (a) BDA 2 breached via scour beneath the dam, determined through field observations and evidenced by turbulent flow downstream of the dam. Image perspective is upstream. (b) BDA 3 breached along the left bank, resulting in minor channel avulsion and flow around the edge of the dam. Image perspective is upstream. (c) Breaching at BDA 4 occurred via overtopping streamflow. Image perspective is aligned with streamflow from left to right.

Tables

Table 1. UAV flight details and camera information for 2017–2019. Information related to the elevation data products generated by Agisoft PhotoScan is presented for 2018 and 2019. Values in italics are error metrics calculated by Agisoft PhotoScan.

UAV flights			
Date	August 15, 2017	August 14, 2018	July 30, 2019
Camera	SONY A5100	SONY A5100	SONY R10
UAV platform	DJI Phantom 4	DJI Phantom 4	DJI M600
Altitude (m)	62.7	66.2	44.2
Images	803	544	601
Image resolution (cm pixel ⁻¹)	1.60	1.73	0.87
Ground control points	11	10	13

JULIANNE (SWEENEY) DAVIS

jsweeney@syr.edu

(585) 967-4648

Syracuse, NY

EDUCATION

M.S., Earth Sciences (anticipated) *June 2020*

Syracuse University, Syracuse, NY

Thesis: Evaluating the geomorphic channel response to beaver dam analogue installation using unoccupied aerial vehicles

B.A., Geological Sciences, *summa cum laude* *Dec. 2016*

State University of New York (SUNY) at Geneseo, Geneseo, NY

Honors Thesis: Using semi-automated workflows in ArcGIS to assess the morphometry and degradation of sub-kilometer scale impact craters at the InSight landing site, Elysium Planitia, Mars

FELLOWSHIPS

NSF NRT Fellowship, Energy Model Program on Water-Energy Research (EMPOWER) at Syracuse University *Aug. 2019 – Aug. 2020*

NSF Graduate Research Fellowship *Sept. 2018 – Aug. 2023*

RESEARCH EXPERIENCE

Graduate Researcher, Syracuse University *Aug. 2018 - Present*

Advisor: Dr. Laura Lautz, Department of Earth Sciences

- Processed visible light unoccupied aerial vehicle (UAV) images to create digital elevation models (DEMs) of the study site in Red Canyon Ranch, Wyoming
- Calculated spatial and temporal changes in channel morphology to understand how beaver dam analogues alter patterns of erosion and deposition

Research Technician (post-graduation), SUNY Geneseo *Jan. – Aug. 2017*

Research Aide (undergraduate), SUNY Geneseo *May 2015 – May 2016*

Advisor: Dr. Nicholas Warner, Department of Geological Sciences

- In both positions, used ArcGIS to rapidly measure the morphometry of ~4,000 impact craters at the landing site of NASA's InSight mission to Mars
- Estimated crater degradation rates to understand the climate history of the landing site and identify potential landing site hazards
- As an undergraduate, began developing workflows in ArcMap to expedite the process of measuring crater morphometry and presented this research at several national conferences
- Post-graduation, refined the workflows, prepared a first-author manuscript and supervised undergraduate researchers who applied the workflow to other regions on Mars

NSF REU Intern, Lamont-Doherty Earth Observatory, Palisades, NY *June – Aug. 2016*

Advisors: Dr. Yael Kiro and Dr. Steven Goldstein, Department of Earth and Environmental Sciences

- Prepared salt, sediment and water samples from the Dead Sea for isotope analyses
- Used uranium isotope ratios to determine the relative contributions of different water sources to the Dead Sea during climatic variations in the Holocene
- Trained in ultraclean laboratory practices, column chemistry and basic use of ICP-MS
- Presented the results at the 2016 American Geophysical Union Annual Meeting

PROFESSIONAL EXPERIENCE

Quality Control Technician, EagleView, Rochester, NY *Feb. – June 2018*

- Performed quality and accuracy assessment on aerial imagery and data products using proprietary image processing programs
- Processed raw imagery to embed positional information using Applanix software
- Trained in basic troubleshooting

Environmental Management Intern, American Rock Salt, Mt. Morris, NY *Jan. – May 2016*

- Participated in federal safety inspections
- Prepared a chemical inventory and compiled the necessary safety data sheets for all underground and aboveground mine facilities
- Assessed state pollutant discharge elimination system (SPDES) permit compliance
- Assisted with public presentations and meetings in anticipation of mine expansion

TECHNICAL SKILLS

Software: MATLAB, R, Visual MODFLOW Flex, ArcGIS, Microsoft Office Suite, Agisoft PhotoScan, Pix4D, Adobe Illustrator

Field: Total station, iButton temperature loggers, Marsh-McBirney flow meter

HONORS AND AWARDS

Outstanding Student Presentation Award, AGU Hydrology Section	<i>Dec. 2019</i>
Runner up in the AGU/NASA Data Visualization and Storytelling Competition	<i>Oct. 2019</i>
Megalith Award for academic excellence and department service, SUNY Geneseo	<i>Dec. 2016</i>
Dwornik Award for Best Undergraduate Poster, GSA Planetary Geology Division	<i>June 2016</i>
Phi Beta Kappa	<i>April 2016</i>

GRANTS

AGU/NASA Data Visualization and Storytelling Competition Travel Grant (\$1,000)	<i>Dec. 2019</i>
EMPOWER Professional Development Seed Grant (\$350)	<i>Dec. 2019</i>
EMPOWER Emerging Interdisciplinary Research Seed Grant (\$3,000)	<i>July 2019</i>
Syracuse University Department of Earth Sciences Merriam Research Grant (\$1,900)	<i>April 2019</i>
Central N.Y. Association for Professional Geologists Student Research Grant (\$500)	<i>Dec. 2018</i>
EMPOWER Professional Development Seed Grant (\$1,500)	<i>Dec. 2018</i>

TEACHING EXPERIENCE

Graduate Teaching Assistant , Syracuse University, Syracuse, NY	
Introductory Earth Sciences Laboratory	<i>Spring 2019</i>
Freshmen-level Oceanography	<i>Fall 2019</i>
Undergraduate Teaching Assistant , SUNY Geneseo, Geneseo, NY	
Introductory Environmental Science Lab	<i>Fall 2016</i>
Historical Geology Lab	<i>Spring 2016</i>
Mineralogy Lab	<i>Fall 2015</i>

WORKSHOPS AND FIELD COURSES

EMPOWER Domestic Field Course: Hubbard Brook, NH and Syracuse, NY	<i>Aug. 2019</i>
Women in Geospatial Sciences, Building Leaders for Tomorrow Workshop	<i>May 2019</i>
Alan Alda Center Science Communication Workshop, Syracuse, NY	<i>Feb. 2019</i>
Partnering with Beaver in Restoration Workshop, Lander, WY	<i>Aug. 2018</i>
SUNY Geneseo International Field Course: Chile	<i>Jan. 2015</i>

SERVICE, LEADERSHIP AND VOLUNTEER EXPERIENCE

AGU Hydrology Section Student Subcommittee (H3S) member	<i>Mar. 2020 – Present</i>
Syracuse University Geology Graduate Organization treasurer and secretary	<i>Aug. 2019 – Present</i>
Frontiers of Science Coordinator	<i>Sept. 2019 – Present</i>
NSF National Research Traineeship Conference Volunteer	<i>Sept. 2019</i>
Syracuse Environmental Challenge Science Fair Judge	<i>May 2019</i>
SUNY Geneseo AIPG Student Chapter co-founder and secretary	<i>June 2015 – Dec. 2016</i>

CONFERENCE ABSTRACTS

Poster Presentations:

Davis, J., Lautz, L.K., Kelleher, C., Russoniello, C. J., and Vidon, P., 2019, Assessing the effects of beaver dam analogues on channel morphology using high-resolution imagery from unoccupied aerial vehicles (UAVs): Abstract H53M-1962 presented at 2019 Fall Meeting, AGU, San Francisco, California, 9–13 December.

Warner, N.H., **Sweeney, J.**, Ganti, V., Golombek, M.P., Lamb, M.P., Ferguson, R.L., and Kirk, R., 2018, Degradation of one-hundred-meter-scale rocky ejecta craters at the InSight landing site on Mars and implications for surface processes and erosion rates: Geological Society of America Abstracts with Programs, v. 50, no. 6.

Golombek, M.P., Warner, N.H., Ganti, V., and **Sweeney, J.**, 2017, Degradation of small impact craters: Erosion rates and Mars climate: Geological Society of America Abstracts with Programs, v. 49, no. 6.

Sweeney, J., Warner, N.H., Golombek, M.P., Kirk, R., Ferguson, R.L., Pivarunas, A., Schwartz, C.H., and Hernandez, D.J., 2017, Constructing a semi-automated method in ArcMap to measure impact crater morphology: 48th Lunar and Planetary Science Conference, abstract 1741.

Sweeney, J., Kiro, Y., and Goldstein, S., 2016, Uranium isotopes as an indicator of the Dead Sea response to Holocene climate shifts: American Geophysical Union Fall Meeting, abstract 2373.

Sweeney, J., Warner, N.H., Golombek, M.P., Kirk, R., Ferguson, R.L., and Pivarunas, A., 2016, Crater degradation and surface erosion rates at the InSight landing site, western Elysium Planitia: 47th Lunar and Planetary Science Conference, abstract 1576.

Warner, N.H., Golombek, M.P., **Sweeney, J.**, and Pivarunas, A., 2016, Regolith thickness estimates from the size frequency distribution of rocky ejecta craters in southwestern Elysium Planitia, Mars: 47th Lunar and Planetary Science Conference, abstract 2231.

Oral Presentation:

Sweeney, J., Warner, N.H., Golombek, M.P., Kirk, R., Ferguson, R.L., Pivarunas, A., Schwartz, C.H., and Hernandez, D.J., 2015, Crater degradation and surface erosion rates at the InSight landing site, Western Elysium Planitia, Mars: Geological Society of America Abstracts with Programs, v. 47, no. 7, p. 603.

OTHER PRESENTATIONS

Davis, J., Assessing the impacts of beaver dam analogues on channel morphology in western rangelands, Central New York Association of Professional Geologists monthly meeting, Syracuse, NY, January 2020.

Davis, J., Eager as a beaver: Imitating nature's ecosystem engineers, Ignite @ AGU, San Francisco, CA, December 2019.
