## Abstract

System  $x_c^-$  ( $Sx_c^-$ ) is a cellular antiporter that links the import of L-cystine with the export of L-glutamate. In the central nervous system (CNS), this export contributes to the ambient glutamate levels found in the synaptic cleft. To wit, a 50% reduction in extracellular glutamate has been demonstrated in animals null for the substrate-specific light chain, xCT. Moreover, in most tissues, including the CNS, cystine import through  $Sx_c^-$  is necessary for the synthesis and maintenance of glutathione (GSH) levels. Given that either a reduction in ambient glutamate levels and/or a redox imbalance involving GSH have been reported to affect synaptic strength and intrinsic neuronal excitability, the main focus of this dissertation was to elucidate whether  $Sx_c^-$  signaling contributes to brain excitatory/inhibitory (E/I) balance *in vivo*. Using chemoconvulsants to uncover excitability changes in  $SLC7A11^{sut/sut}$  mice — mice that are null for  $Sx_c^-$  because of a spontaneous mutation in exon 12 of  $SLC7A11$  — we uncovered a sex-independent alteration in neuronal excitability. Specifically, we found that both female and male  $SLC7A11^{sut/sut}$  mice had lower convulsive seizure thresholds than their wild-type ( $SLC7A11^{+/+}$ ) littermates after acute challenge with two pharmacologically distinct chemoconvulsants: the glutamate receptor agonist, kainic acid (KA), or the GABA<sub>A</sub> receptor antagonist, pentylenetetrazole (PTZ). Paradoxically, after repeated/repeated/chronic administration of the same chemoconvulsants,  $SLC7A11^{sut/sut}$  mice exhibit signs of hypo-excitability, a response polar opposite to that which occurs in  $SLC7A11^{+/+}$  littermate controls. Whether the aberrant neuronal excitability in  $SLC7A11^{sut/sut}$  mice occurred in association with alterations in brain morphology – at the gross, cellular, and sub-cellular level – or with alterations in redox balance or plasma

membrane protein expression levels, was also investigated. Overall, our data demonstrate that neuronal excitability in *SLC7A11<sup>sut/sut</sup>* mice provoked by chemoconvulsant challenge deviates from that of *SLC7A11<sup>+/+</sup>* littermates in a complex manner that differs in sign depending on the chemoconvulsant dosing paradigm employed. Moreover, mutations in *Sxc<sup>-</sup>* trigger sex-dependent changes in redox status, brain morphology, and plasma membrane protein expression, any or all of which could contribute to the observed E/I imbalance in *SLC7A11<sup>sut/sut</sup>* mice.

Regulation of *in vivo* excitatory/inhibitory balance by the  
cystine/glutamate exchanger system  $x_c^-$

## Acknowledgements

First and foremost, I want to thank my PhD advisor Dr. Sandra Hewett. With her support and guidance, I was able to pursue a novel line of inquiry that I found interesting for my dissertation research. Her rigorous training in experimental design, scientific writing, and oral presentations will serve me throughout my career, and I am grateful for the many hours that she has spent mentoring me in these important skills. Having pursued a doctorate under Dr. Hewett, I have been and will continue to be well-prepared to present my work to the broader neuroscience community and to have rewarding discussions with colleagues. I am excited for what lies ahead in my career - in large part because Dr. Hewett's contagious enthusiasm for science has inspired my own.

I would like to thank my committee members, including my informal co-advisor, Dr. Jim Hewett, whose insight and expertise of the seizure models used in this dissertation have been an invaluable resource. Drs. Frank Middleton and Melissa Pepling were instrumental members of my research committee, whose thought-provoking questions drove my scientific thoughts in novel directions. My sincere thanks also goes to Dr. Jessica MacDonald, who allowed me to access her laboratory facilities in order to pursue my neuronal morphological analyses and who, as a member of my defense committee, provided thoughtful feedback on my dissertation.

My colleagues in the Hewett<sup>2</sup> labs have provided a supportive environment over the years – and I would like to especially thank Dr. Yan He, Trista Thorn, Dr. Jingxue Shi, Yifan Gong, Twinkle Chowdury, Megan Leblanc, Valarie Vought, Matthew Allen, and Spandita Dutta for their assistance, expertise, and friendship inside and outside of

the lab. I will miss our coffee trips dearly, as well as coming into work each day to a lab full of colleagues that truly cared for and looked out for one another. Moreover, the departmental grad students – many of whom were roommates, friends, and confidants – were important in keeping me well-balanced. Our support of one another in our shared endeavor towards a graduate degree has been integral in my success.

Finally, I would like to thank my family – especially my parents, Laura and Shahram, and brother – for their support in my pursuit of a PhD – even though it was on the opposite side of the country. My parents have always taught us to pursue knowledge, and my work ethic – which was learned by watching their examples growing up – has allowed for me to successfully reach the PhD finish line. Last but certainly not least, I thank my husband Will. Though often times he was 3,445 miles away, his unwavering love and support (as my #1 fan), as well as his daily words of encouragement for five years, have meant the world to me.

AMPA	alpha-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid
CA1	Cornu Ammonis 1
CA3	Cornu Ammonis 3
cDNA	Complementary DNA
CNS	Central nervous system
Cys	Cysteine
CySS	Cystine
DG	Dentate Gyrus
EAAT	Excitatory amino acid transporter
E/I	Excitatory/inhibitory
EPSC	Excitatory postsynaptic current
EPSP	Excitatory postsynaptic potential
GABA	gamma-aminobutyric acid
GSH	Glutathione
GSSG	Glutathione disulfide
i.p.	Intraperitoneal
iGluRs	Ionotropic glutamate receptors
IPSC	Inhibitory postsynaptic current
IPSP	Inhibitory postsynaptic potential
KA	Kainic acid
KARs	Kainic acid receptors
KCC2	Potassium/chloride (K <sup>+</sup> /Cl <sup>-</sup> ) cotransporter
K <sub>m</sub>	Substrate concentration at which velocity is 1/2 of V <sub>max</sub>
LTP	Long term potentiation
Mg <sup>2+</sup>	Magnesium
mGluRs	Metabotropic glutamate receptors
MMSS	Median maximal seizure score
NAC	N-acetylcysteine
NMDA	N-methyl-D-aspartate receptors
PTZ	Pentylentetrazole
qPCR	Quantitative real-time polymerase chain reaction
SE	Status epilepticus
SLC7A11	Solute carrier family 7 member 11
Sx <sub>c</sub> <sup>-</sup>	System x <sub>c</sub> <sup>-</sup>
VGATs	Vesicular GABA transporters
xCT	Light chain subunit of Sx <sub>c</sub> <sup>-</sup> transporter
4f2hc	Heavy chain of the surface antigen 4f2

**Chapter 1: Introduction**

## 1.1 Overview

In several brain disorders including autism, stroke, and epilepsy an imbalance between the excitatory and inhibitory (E/I) neurotransmitter systems exists. Understanding fully the cellular and molecular processes that underlie normal, physiological synaptic transmission is the first step in determining how such aberrations might be countered to provide affected individuals with E/I imbalance symptomatic relief. This dissertation focuses on the role of the cystine/glutamate antiporter System  $x_c^-$  ( $Sx_c^-$ ) — which exports glutamate and imports cystine, the latter of which is the rate-limiting substrate for the synthesis of the thiol antioxidant glutathione — in maintenance of E/I balance.

## 1.2 The cystine/glutamate antiporter System $x_c^-$ ( $Sx_c^-$ )

$Sx_c^-$  was first described in 1980 by Bannai and Kitamura who demonstrated that the  $Na^+$ -independent uptake of cystine into cultured human diploid fibroblasts was inhibited by glutamate (and *vice versa*) (Bannai & Kitamura 1980).  $Sx_c^-$  is an amino acid antiporter that imports L-cystine and exports L-glutamate in a  $Na^+$ -independent,  $Cl^-$ -dependent, 1:1 stoichiometric ratio (Bannai 1986, Bannai & Kitamura 1980). Cystine/glutamate exchange is electroneutral, with transport limited to the anionic form of these amino acids. The direction of exchange is determined by the substrate concentration gradient and is independent of membrane potential (Bannai 1986). Though  $Sx_c^-$  is capable of transporting either amino acid in either direction, rapid kinetics of excitatory amino acid transport (EAAT) systems and intracellular reductases maintain relatively low levels of extracellular glutamate and intracellular cystine, respectively, whereas intracellular glutamate levels are typically in the millimolar range,

conferring the aforementioned directionality of transport (Bannai & Kitamura 1980, Hertz et al 1988).

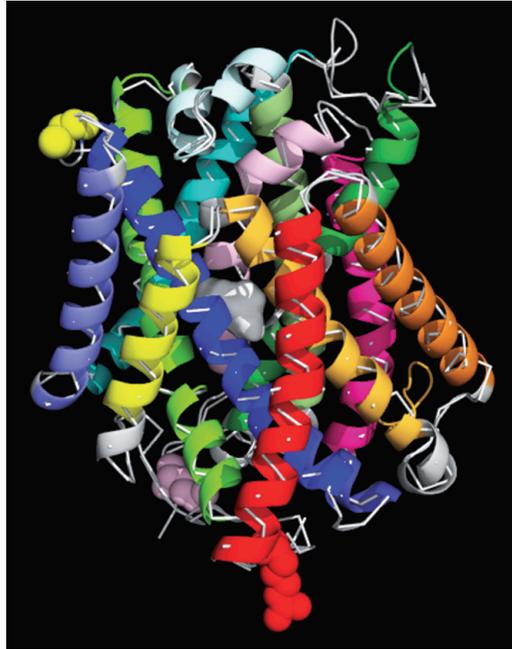

### **1.2.1 $Sx_c^-$ structure**

Identification of  $Sx_c^-$  by expression cloning revealed it is a heteromeric amino acid transporter (HAT) and therefore composed of a light chain and a heavy chain covalently linked through a disulfide bridge (Sato et al 1999). The light (catalytic) chains of HATs, also known as glycoprotein-associated amino acid transporters (gpaATs), are members of the solute carrier 7 (SLC7) family and confer their substrate specificity (Verrey et al 2004). HAT light chains must associate with a glycoprotein heavy chain of the SLC3 family in order to allow for surface expression (Verrey et al 2004). With respect to  $Sx_c^-$  the gpaAT light chain is xCT, encoded by the solute carrier gene *SLC7A11*, and the heavy chain is 4f2hc (4f2 cell-surface antigen heavy chain, also known as cluster of differentiation 98 [CD98]), encoded by *SLC3A2* (Bassi et al 2001, Sato et al 1999). While xCT is specific to  $Sx_c^-$ , 4f2hc forms a heterodimer with at least five other gpaAT light chains within the HAT family (Verrey et al 2004).

In humans, the *SLC7A11* gene is located on chromosome 4q28-31, producing a 40 kDa protein of a predicted 501 amino acids (Bassi et al 2001). The encoded xCT protein shares 93-96% similarity and 89% identity to mouse xCT protein, which is a predicted 502 amino acids (Bassi et al 2001, Sato et al 1999). The mouse *SL7A11* gene maps on chromosome 3 (Lane 1988). As with other proteins of the HAT family, xCT has 12 putative transmembrane domains and is thus highly hydrophobic (Gasol et al 2004). Both the N- and C-termini are intracellularly localized, and there is a reentrant loop

between transmembrane domains 2 and 3 (Gasol et al 2004). This reentrant loop is believed to be a site of substrate binding, as biotinylation of His<sup>110</sup> at the apex of loops 2 and 3 does not occur in the presence of cystine, glutamate, or the non-transportable Sx<sub>c</sub><sup>-</sup> inhibitor, (s)-4-carboxyphenylglycine (4-CPG) (Gasol et al 2004). Another potential substrate binding site is near Cys<sup>327</sup> in the middle of the eighth transmembrane domain; in a study by Jimenez-Vidal and colleagues, the authors proposed a scenario whereby small side-chains at this position are permissive to substrate binding and translocation whereas bulky amino acids inflict steric hindrance to transporter activity (Jiménez-Vidal et al 2004). More recently, precrystallization screening of xCT bacterial orthologs and subsequent identification of a representative amino acid, polyamine, and organocation (APC) transporter revealed greater insight into HAT structure (Shaffer et al 2009). Further substrate permeation residues were identified including human xCT residue Arg<sup>135</sup>, suggested to be a binding-site of the substrate's  $\gamma$ -carboxylate entity (Shaffer et al 2009). Using the crystal structure of this APC transporter, Bridges et al proposed a novel three-dimensional representation of xCT protein structure using protein threading of human xCT (Fig. 1.1) (Bridges et al 2012b).

The *SLC3A2* gene encoding the type II membrane glycoprotein 4f2hc is located on chromosome 11q12-13 in humans (chromosome 19 in mouse) and produces a  $\approx$ 94 kDa glycosylated protein (72 kDa unglycosylated) of approximately 526-529 amino acids in humans (Francke et al 1983, Lumadue et al 1987, Quackenbush et al 1987). This protein shares 75% amino acid identity with mouse 4f2hc, which has a predicted 526 amino acids (Parmacek et al 1989). Mouse 4f2hc consists of a 428 amino acid

**Figure 1.1 xCT homology model**

xCT homology model depicting xCT protein in its inwardly-facing Apo form as proposed by Bridges et al 2012. The human xCT protein sequence was threaded over the crystal structure of a bacterial xCT homolog, ApcT (Shaffer et al 2009). Each helical ribbon represents a transmembrane domain of xCT, while the white thread demonstrates the ApcT structure. The truncated N and C termini are depicted by light pink and red spheres, respectively. Yellow spheres depict the conserved cysteine residue (Cys<sup>158</sup>), located between pore loops three and four of the xCT protein, that forms a bond with 4f2hc. Adapted from (Bridges et al 2012b).

extracellular C-terminal domain, a 23 amino acid transmembrane domain, and a 75 amino acid N-terminal cytoplasmic domain (Parmacek et al 1989). The bulky C-terminus is heavily glycosylated, with nine potential N-linked glycosylation sites in mouse and four such sites in human (Parmacek et al 1989). Northern blot analysis has revealed that 4f2hc is ubiquitously expressed in mouse, with highest levels of expression found in kidney, lung, spleen, testis, and brain (Parmacek et al 1989). It is involved in a diverse array of biological processes including integrin signaling, cell adhesion, and cell activation and proliferation (Bron et al 1986, Fenczik et al 1997, Nguyen et al 2008). The latter role is supported by evidence that its expression is induced upon fibroblast activation and maintained at high expression levels throughout the cell cycle (Parmacek et al 1989). Given that 4f2hc is abundantly expressed throughout the body, Sx<sub>c</sub><sup>-</sup> transport activity is tied to the expression and availability of the light-chain subunit xCT (Verrey et al 2004).

Multiple studies have confirmed that xCT forms a disulfide bridge with 4f2hc at a single, conserved cysteine residue (Cys<sup>158</sup>) located between pore loops three and four of the xCT protein (Bassi et al 2001, Bridges et al 2012b, Sato et al 1999). Experiments using cysteine-to-serine mutagenesis or reducing agents with 4f2hc/HAT dimers suggest that this light-chain residue interacts with Cys<sup>109</sup> of 4f2hc (Estévez et al 1998, Torrents et al 1998). Intriguingly, the functional role of this covalent linkage remains elusive. This cys-cys interaction is not required to induce transporter activity in at least one other HAT; cysteine-to-serine mutagenesis at the disulfide bridge in LAT1, an aromatic and branched-chain amino acid HAT, results in functional transport activity in both *Xenopus* oocytes and mammalian cells (Nakamura et al 1999, Wagner et al 2000).

Whether the same is true for the xCT/4f2hc disulfide bridge remains to be investigated. Furthermore, exactly how 4f2hc interacts with xCT is unknown, though it too may share similar characteristics with other HATs. In the case of LAT2, a neutral amino acid transporter, the 4f2hc ectodomain interacts with its extracellular loops, covering the extracellular surface of the light chain protein and increasing transporter stability (Rosell et al 2014).

As mentioned previously, 4f2hc can interact with five other gpaAT light-chains at Cys<sup>109</sup> besides xCT; LAT1 (*SLC7A5*) (Kanai et al 1998, Mastroberardino et al 1998), LAT2 (*SLC7A8*) (Pineda et al 1999, Rossier et al 1999, Segawa et al 1999), system asc1 (small neutral amino acid transporter, *SLC7A10*) (Fukasawa et al 2000), and the cationic amino acid transporters  $\gamma$ +LAT1 (*SLC7A7*) and  $\gamma$ +LAT2 (*SLC7A6*) (Pfeiffer et al 1999, Torrents et al 1998) [for detailed reviews see (Palacín et al 2005, Verrey et al 2004)]. All 4f2hc-associated light-chains require the heavy chain to translocate to the plasma cell membrane and induce transporter activity. With respect to  $Sx_c^-$ , this was demonstrated in *Xenopus* oocytes whereby co-injection of xCT and 4f2hc cRNA induced transport of L-glutamate and L-cystine and resulted in expression of xCT at the oocyte plasma membrane (Bassi et al 2001, Sato et al 1999). In contrast, injection of xCT or 4f2hc alone did not induce transport activity, with the former scenario resulting in intracellular retention of xCT (Bassi et al 2001, Sato et al 1999). Induction of cystine/glutamate exchange can also be induced by co-injection of mouse, but not human, cRNA for xCT and rBAT, a heavy chain with significant homology to 4f2hc (Bassi et al 2001, Wang et al 2003). Whether xCT associates with rBAT *in vivo* has yet to be ascertained.

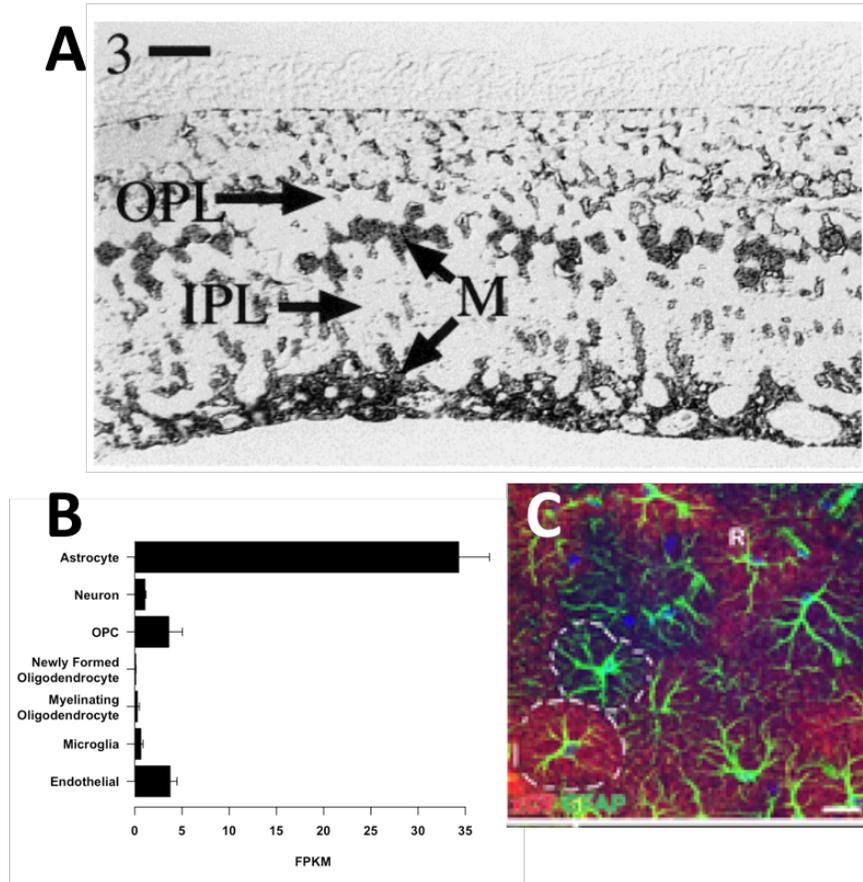

### **1.2.2 $Sx_c^-$ expression**

Expression of xCT mRNA and protein have been detected throughout the body suggesting that  $Sx_c^-$  plays a role in maintaining cellular health in a variety of biological processes. Northern blot and quantitative polymerase chain reaction (PCR) analyses have revealed widespread xCT mRNA expression in the pancreas, intestine, ovary, spleen, and stomach (Bassi et al 2001, Dave et al 2004). Using an xCT specific antibody confirmed by xCT siRNA knockdown in HT22 cells, Burdo and colleagues also demonstrated xCT protein expression in kidney (Burdo et al 2006).

Within the mouse central nervous system (CNS), *in situ* hybridization studies have revealed xCT mRNA expression at the brain/cerebral spinal fluid (CSF) borders including the cerebral ventricles, meninges, and circumventricular organs such as the area postrema and subfornical organ (Sato et al 2002). Furthermore, robust expression of xCT mRNA was found in most major brain regions including in the cerebral cortex, putamen, and medulla, with xCT protein detected in cortex, hippocampus, and striatum (Sato et al 2002, Shih et al 2006). Weak xCT mRNA expression was found in the choroid plexus, thalamus, cerebellum, brainstem, and nucleus of the solitary tract, with no expression detected in mouse brain vasculature (Sato et al 2002). Interestingly, xCT protein is present in human brain vasculature, suggesting that cystine/glutamate exchange across the blood brain barrier may be species specific (Burdo et al 2006).

Despite the scarcity of reliable antibodies against xCT protein – largely owing to its hydrophobicity bestowed by its 12 transmembrane domains – the cell-type specificity of xCT expression in the CNS is becoming increasingly better understood. While  $Sx_c^-$  is expressed in cultured microglia (Jackman et al 2010, Piani & Fontana 1994), neurons

(Burdo et al 2006, Dun et al 2006, Jackman et al 2010, Murphy et al 1990), and the HT22 neuronal cell line (Lewerenz et al 2003), there is a growing consensus that astrocytes are the primary cell types expressing  $Sx_c^-$  in the mature brain *in vivo* (Fig. 1.2). Nearly 20 years ago, Pow and colleagues elucidated the cell-type specificity of  $Sx_c^-$  activity using an antibody against the xCT substrate inhibitor,  $\alpha$ -aminoadipate, in rat brain slice (Pow 2001). Substrate accumulation occurred in glia – specifically Bergmann glia, radial glia, and astrocytes – and was conspicuously absent from neurons and oligodendrocytes (Pow 2001). Furthermore, rodent astrocytes in cell culture express xCT, as do human glioma cell lines (Bender et al 2000, Burdo et al 2006, Cho & Bannai 1990, Gochenauer & Robinson 2001, Pow 2001, Ye & Sontheimer 1999), and transcriptome data from both human and mouse cortex indicates that xCT is enriched in astrocytes as compared to other parenchymal cells (Zhang et al 2014, Zhang et al 2016b). More recently, Ottestad-Hansen and colleagues engineered an xCT specific antibody and determined that  $Sx_c^-$  is expressed throughout the adult mouse brain parenchyma in a subpopulation of astrocytes – but not any other cell type investigated including neurons, microglia, and oligodendrocytes (Ottstad-Hansen et al 2018). Confirming *in situ* studies, xCT labeling was found concentrated at the brain/blood/cerebral spinal fluid periphery, as well as in most major brain regions including cortex, thalamus, hypothalamus, striatum, and hippocampus – where labeling intensity was greatest in the molecular layer of the dentate gyrus and the *stratum lacunosum moleculare* (Ottstad-Hansen et al 2018). Finally, the concentration of xCT protein was estimated to be comparable to that of EAAT3 (0.013 mg/g hippocampal

**Figure 1.2 *Sxc* is predominantly localized to CNS astrocytes**

(A) An antibody against the xCT substrate inhibitor,  $\alpha$ -aminoadipate, demonstrated that  $\alpha$ -aminoadipate uptake occurred mainly in Muller glia cells (M) and was excluded from synaptic terminals in the outer (OPL) and inner (IPL) plexiform layers of rat retina. (B) Mouse cortical transcriptome data from the Barres lab indicates that astrocytes are the predominant cell types expressing *SLC7A11* in mouse cortex (OPC: oligodendrocyte precursor cell; FPKM: Fragments Per Kilobase of transcript per Million mapped reads). (C) Ottestad-Hansen and colleagues observed that xCT expression (red) exclusively co-localized with a subset of GFAP (green) expressing astrocytes in CA1 hippocampus (shown) and throughout the CNS (not shown). Figures adapted from [A (Pow 2001), B (Zhang et al 2014), and C (Ottestad-Hansen et al 2018)].

tissue), suggesting that xCT abundance is sufficient to contribute to brain function (Holmseth et al 2012, Ottestad-Hansen et al 2018).

### **1.2.3. $Sx_c^-$ function**

#### *1.2.3.1 Use of xCT null mice to characterize $Sx_c^-$ function in vivo*

Insight into the *in vivo* contribution of  $Sx_c^-$  signaling has been possible due to the use of genetic xCT loss of function mouse models. Sato and colleagues genetically engineered the first global xCT knock-out ( $xCT^{-/-}$ ) mouse on the C57BL/6 background by removing the ATG start codon in exon 1 of *SLC7A11* (Sato et al 2005). These mice lack glutamate-sensitive cystine uptake as well as xCT transcript and protein in all tissues examined, including in brain and thymus where constitutive expression is normally observed (McCullagh & Featherstone 2014, Sato et al 2005).  $xCT^{-/-}$  mice, however, were healthy in appearance, fertile, and all of the major organs examined – including the kidney, pancreas, lung, liver, and brain – had no apparent abnormalities (Sato et al 2005). A second xCT loss of function mouse was engineered by inducing an in-frame TGA stop codon in exon 10 of *SLC7A11* in C57BL/6 mice using *N*-ethyl-*N*-nitrosourea (ENU) mutagenesis (Nabeyama et al 2010). Finally, a spontaneous mutation in *SLC7A11* gave rise to the subtle gray (*sut*) mutant mice on the C3H/HeSnJ background, henceforth referred to as the *SLC7A11<sup>sut/sut</sup>* mice (Chintala et al 2005). The *SLC7A11<sup>sut/sut</sup>* mice have a large deletion (481,280 base pairs) that extends from intron 11 to exon 12 and into the *SLC7A11* intergenic region neighboring the *Pcdh18* gene, resulting in a new stop codon in exon 12' (Chintala et al 2005). Important for this dissertation, no xCT protein or transcript have been detected in the brains of

*SLC7A11<sup>sut/sut</sup>* mice (Chintala et al 2005, McCullagh & Featherstone 2014). These mice are fertile and healthy in appearance (Hewett lab unpublished observations).

*SLC7A11<sup>sut/sut</sup>* mice have a subtle gray coat color, which is a result of decreased pheomelanin (red/yellow) pigment production due to reduced  $Sx_c^-$ -mediated cystine import into melanocytes (Chintala et al 2005). Interestingly, Shih et al found that *SLC7A11<sup>sut/sut</sup>* mice exhibit gross brain atrophy by 13 weeks of age compared to wild-type C3H/HeSnJ mice maintained on a separate, homozygous background as demonstrated by a reduction in hemisphere and striatal area, cortical thinning, and ventricular enlargement (Shih et al 2006). However, the observed neurodegeneration in this particular *SLC7A11<sup>sut/sut</sup>* sub-strain may be attributable to genetic drift from the authors wild-type colony as a result of maintaining homozygous colonies (Henderson 1997, Masel 2011). Indeed, *SLC7A11<sup>sut/sut</sup>* mice derived from heterozygous breeding units do not exhibit gross brain atrophy when compared to wild-type littermate controls (Chapter 2), suggesting the phenotype reported by Shih et al is not exclusively due to loss of the *SLC7A11* gene.

### 1.2.3.2 Cellular cystine supplier

$Sx_c^-$ -mediated cystine import is fundamental in maintaining the extracellular and intracellular redox balance as it provides the rate-limiting substrate (cystine) for the biosynthesis of the thiol antioxidant glutathione (GSH;  $\gamma$ -glutamylcysteinylglycine) (Sato et al 1998) and it facilitates the cysteine/cystine redox coupling across the cell plasma membrane (Banjac et al 2008). Once transported intracellularly, cystine is rapidly reduced into two cysteine molecules that can be incorporated in proteins, GSH, or

exported via the neutral alanine-serine-cysteine transporters (system ASC) in maintenance of the cystine/cysteine redox couple (Banjac et al 2008, Sato et al 1998).

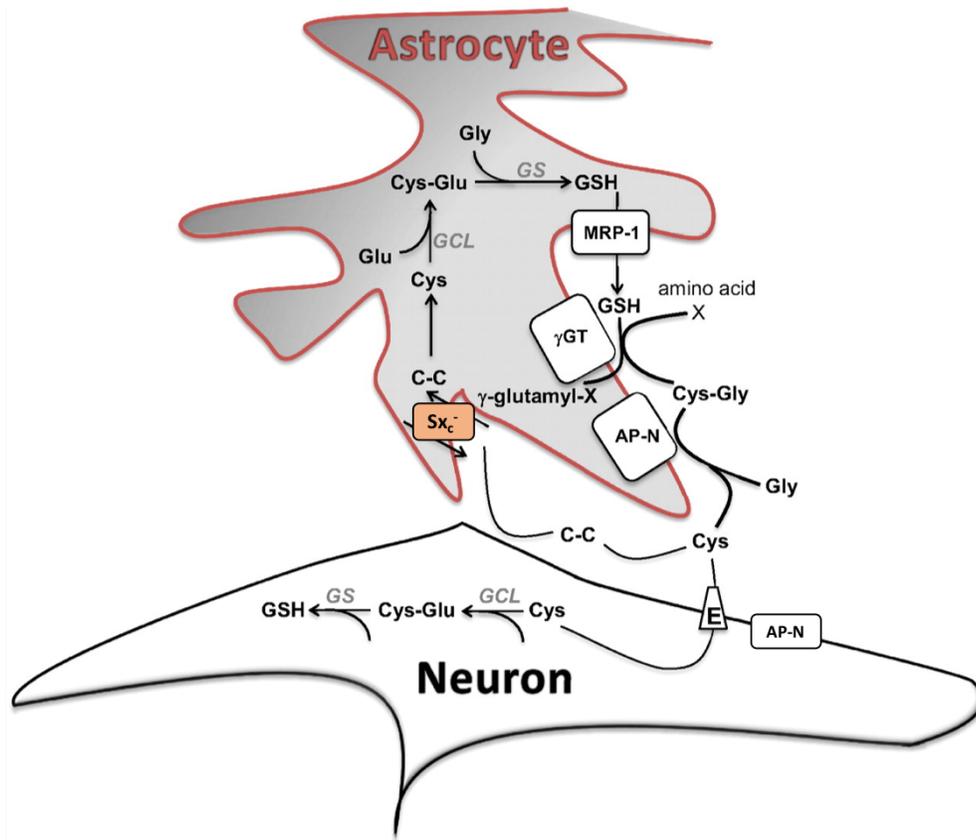

It should be noted that cells throughout the body can accumulate cyst(e)ine via several alternative mechanisms. *De novo* cysteine synthesis from methionine via the transsulfuration pathway represents a mechanism by which cells can obtain cysteine, and evidence suggests this pathway may be particularly active in supplying cysteine for GSH synthesis under conditions of oxidative stress or when  $Sx_c^-$  transport is limited (McBean 2012). In addition, several cystine transporters are expressed throughout the body, including system  $b^{0,+}$  and the aspartate/glutamate transporter 1 (AGT1), responsible for cystine reabsorption in the renal proximal tubules (Fernández et al 2002, Nagamori et al 2016). In the CNS, other known cysteine transporters include system  $X_{AG}^-$  transporters EAAT2 and EAAT3, expressed in astrocytes and/or neurons (Chen & Swanson 2003, Watts et al 2014), the ASC transporters 1 and 2, predominantly expressed in astrocytes (Fernández et al 2005, Fotiadis et al 2013, Nagamori et al 2016), the aromatic preferring amino acid transporter (ArpAT) (Fernández et al 2005), the system A  $Na^+$ -coupled neutral amino acid transporters 1 and 2 (SNAT1 and SNAT2) (Mackenzie & Erickson 2004), and the neurotransmitter transporter 4 (NTT4) (Zaia & Reimer 2009).

Despite the prevalence of cyst(e)ine transporters, GSH synthesis in CNS astrocytes is tightly linked to  $Sx_c^-$ -mediated cystine import. In fact, in their seminal characterization of  $Sx_c^-$ -mediated cystine/glutamate exchange, Bannai and Kitamura demonstrated that approximately 15% of  $Sx_c^-$ -mediated cystine import is incorporated into GSH within five minutes of transport (Bannai & Kitamura 1980). This is further

exemplified by evidence demonstrating enhanced  $Sx_c^-$  activity occurs in association with increases in GSH (Hosoya et al 2002, Sasaki et al 2002), and that inhibition of  $Sx_c^-$  diminishes intracellular GSH stores (Kato et al 1992, Sagara et al 1996).

GSH synthesis takes place intracellularly in the cytosol in a two-step reaction (Fig. 1.3) (Meister 1974). In the first step, glutamate and the rate-limiting substrate cysteine are used to form the dipeptide  $\gamma$ -glutamylcysteinyl in a reaction catalyzed by  $\gamma$ -glutamylcysteinyl synthetase (glutamate-cysteine ligase). In the second step, glutathione synthetase catalyzes the formation of  $\gamma$ -glutamylcysteinylglycine (GSH) from  $\gamma$ -glutamylcysteinyl and glycine; with the final product (GSH) capable of feedback inhibiting  $\gamma$ -glutamylcysteinyl synthetase (step one) (Meister 1974, Richman & Meister 1975). In fulfillment of its role as an antioxidant, GSH either directly detoxifies radicals or serves as a cofactor for the antioxidant enzyme glutathione peroxidase in the reduction of peroxides (Chance et al 1979, Saez et al 1990, Winterbourn & Metodiewa 1994). In either case, GSH oxidation results in a glutathione disulfide (GSSG) product, which itself is a substrate for glutathione reductase in a reaction that regenerates GSH [reviewed in (Dringen et al 2000)]. In this way, GSH molecules synthesized intracellularly and used for detoxification are recycled. Conversely, GSH molecules used as a substrate for intracellular glutathione-S-transferases (GST) lower the intracellular GSH concentration, as does GSH export [reviewed in (Dringen et al 2000)].

In the CNS, increased astrocyte GSH production is intimately linked to decreased oxidative stress susceptibility in neurons (Gegg et al 2005). Interestingly, astrocytes export 10% of their GSH per hour (Minich et al 2006). Once extracellular, GSH may serve as a substrate for the ectoenzyme  $\gamma$ -glutamyl transpeptidase ( $\gamma$ GT) and its

**Figure 1.3 GSH metabolism and transport**

Astrocyte  $Sx_c^-$  imports cystine (C-C) which, once intracellular, is rapidly reduced to cysteine (Cys). Glutamate-cysteine ligase (GCL; also known as  $\gamma$ -glutamylcysteinyl synthetase) catalyzes the formation of glutamate (Glu) and Cys to  $\gamma$ -glutamylcysteine (Cys-Glu). Glycine (Gly) is added to the dipeptide by GSH synthetase (GS) to form the tripeptide glutathione (GSH). Astrocytic export of GSH is facilitated through the multidrug resistance protein 1 (MRP-1) transporter. Once extracellular, GSH is cleaved by  $\gamma$ -glutamyltransferase ( $\gamma$ -GT) into cysteinylglycine (Cys-Gly). Aminopeptidase N (AP-N) promotes further breakdown of cysteinylglycine into glycine and cysteine. Cysteine is taken up into neurons via EAATs (E), where it is metabolized into GSH. Alternatively, the extracellular oxidation of cysteine into cystine promotes  $Sx_c^-$ -mediated uptake into astrocytes. Adapted from (Bridges et al 2012a).

product, cysteinylglycine (CysGly), can serve as a GSH precursor (Taniguchi & Ikeda 1998). Neurons express an ectopeptidase of their own (aminopeptidase N) which allows them to utilize CysGly by taking up its constituent amino acids (cysteine and glycine) to be used for GSH synthesis intracellularly (Dringen et al 2001). Thus, astrocytic GSH production is not only used as a cell-autonomous thiol antioxidant, but its export confers protection to neurons as well. Apart from its role as an antioxidant, GSH is perhaps the most important cellular thiol that participates in signal transduction and regulates cellular metabolism and proliferation, gene expression, cytokine and growth factor production, and the function of proteins with redox-modification residues (Dringen 2000, Klatt & Lamas 2000, Poot et al 1995, Shih et al 2006, Stamler & Hausladen 1998).

Since astrocytes derive the majority of their cystine from  $Sx_c^-$  transport, and cyst(e)ine is the rate-limiting substrate in the synthesis of GSH and forms a redox couple (cysteine/cystine) on its own, it follows that  $Sx_c^-$  is involved in maintaining redox balance *in vivo*. Indeed, male xCT-deficient mice on a C57BL/6 background have a plasma redox imbalance characterized by elevated CySS and decreased GSH levels as compared to wild-type control animals (Sato et al 2005). Intriguingly, male xCT null mice on this same background do not have a hippocampal or striatal redox imbalance as evidenced by lack of oxidative stress markers and similar GSH levels as compared to wild-type controls (De Bundel et al 2011, Massie et al 2011b). Furthermore, the striatum of male xCT null mice have similar expression levels of oxidative stress-related markers HO-1, HNE, and NT as compared to wild-type controls following a 6-hydroxydopamine (6-OHDA) injection (Massie et al 2011b). Whether a compensatory

expression of other cysteine transporters in xCT null mice explains their lack of brain redox imbalance is not known.

### 1.2.3.3 Regulation of ambient extracellular glutamate levels

Evidence from xCT null animals has demonstrated that  $Sx_c^-$ -derived glutamate contributes to the extracellular glutamate pool that bathes the CNS *in vivo*. In male xCT<sup>-/-</sup> mice, extracellular glutamate levels are decreased by  $\approx 40\%$  in the hippocampus and  $\approx 70\%$  in the striatum as compared to wild-type C57BL/6 controls (De Bundel et al 2011, Massie et al 2011b). Similarly, in male *SLC7A11<sup>sut/sut</sup>* mice, extracellular glutamate levels are decreased in the striatum by  $\approx 50\%$  as compared to wild-type C3H/HeSnJ mice (McCullagh & Featherstone 2014). Interestingly, extracellular glutamate levels in male *SLC7A11<sup>sut/sut</sup>* cerebellum are comparable to wild-type controls, suggesting that the contribution of  $Sx_c^-$  to ambient glutamate occurs in a brain region-dependent manner (McCullagh & Featherstone 2014). These findings are in line with results from the Danbolt lab showing relatively weak cerebellar xCT expression levels as compared to forebrain (Ottestad-Hansen et al 2018). Of note, the one study that investigated extracellular glutamate levels in both male and female  $Sx_c^-$  null mice found that male, but not female, *SLC7A11<sup>sut/sut</sup>* mice have decreased extracellular glutamate levels in the striatum as compared to wild-type sex-matched controls (Borra et al 2014). Interestingly, the authors did find a  $\approx 70\%$  decrease in striatal extracellular glutamate levels in wild-type females versus males, giving rise to the idea that there are sex-differences in glutamate physiology and perhaps,  $Sx_c^-$ -mediated glutamate release (Borra et al 2014).

Regulation of ambient extracellular glutamate levels by  $Sx_c^-$  is conserved across species. In *Drosophila*, genetic disruption of the xCT homolog, *genderblind*, results in a  $\approx 50\%$  reduction in hemolymph glutamate levels (Augustin et al 2007, Piyankarage et al 2008). Furthermore, reverse dialysis of the xCT pharmacological inhibitors homocysteic acid or (S)-4-carboxyphenylglycine (CPG) leads to a 60% decrease in extracellular glutamate levels in rat striatum (Baker et al 2002).

The role of ambient glutamate appears to be multifaceted (section 1.3.3.2), and several mechanistic studies have shed light on whether  $Sx_c^-$ -derived glutamate contributes to physiological neural transmission. In *genderblind* mutants, Augustin and colleagues demonstrated that a reduction in glutamate levels occurs in association with increased ionotropic glutamate receptor immunoreactivity and enhanced spontaneous excitatory junction current amplitudes at the neuromuscular junction (NMJ) (Augustin et al 2007). Moreover, bathing wild-type larval NMJs in abnormally low levels of glutamate was sufficient to phenocopy glutamate receptor expression levels in *genderblind* mutants (Augustin et al 2007). More recently, this same group confirmed  $Sx_c^-$ -derived glutamate controls synaptic strength at the mouse hippocampal CA3-CA1 synapse by demonstrating that slices derived from male  $xCT^{-/-}$  mice have enhanced AMPA receptor immunoreactivity and spontaneous and evoked excitatory postsynaptic currents (EPSCs) in CA1 as compared to wild-type control slices (Williams & Featherstone 2014). Similar to their studies in *Drosophila*, the authors phenocopied their  $xCT^{-/-}$  electrophysiology findings by incubating wild-type slices in Glu-free artificial cerebrospinal fluid or by using the  $Sx_c^-$  inhibitor (S)-4-carboxyphenylglycine (4-CPG), providing evidence that glutamate released via  $Sx_c^-$  modulates synaptic strength

(Williams & Featherstone 2014). Finally,  $Sx_c^-$ -derived glutamate negatively modulates release of synaptic glutamate and dopamine in the nucleus accumbens and striatum, respectively, by exerting glutamatergic tone on group II metabotropic glutamate receptors in male rats (Baker et al 2002, Moran et al 2005). Thus, evidence across multiple species suggests that  $Sx_c^-$ -derived ambient glutamate contributes to the delicate balance between excitatory and inhibitory neurotransmission (E/I balance) that exists in the CNS.

#### **1.2.4 Role of $Sx_c^-$ in CNS function**

While  $Sx_c^-$  signaling has been implicated in a number of disorders and disease states associated with a primary or secondary excitatory/inhibitory (E/I) imbalance including multiple sclerosis (Domercq et al 2007, Evonuk et al 2015, Pampliega et al 2011), amyotrophic lateral sclerosis (Albano et al 2013, Mesci et al 2014), Huntington's disease (Frederick et al 2014), Alzheimer's disease (Barger & Basile 2001, Qin et al 2006, Zhang et al 2016a), Parkinson's disease (Bentea et al 2015b, Massie et al 2011b, Massie et al 2008), cerebral ischemia (Fogal et al 2007, Soria et al 2014), addiction (Baker et al 2003, Knackstedt et al 2010, Moran et al 2005), epilepsy (Lewerenz et al 2014, Takaki et al 2008), and glioblastoma multiforme (Chung et al 2005, Takeuchi et al 2012, Ye et al 1999, Ye & Sontheimer 1999) and its associated epileptiform activity (Buckingham et al 2011, Robert et al 2015), a growing body of evidence suggests that  $Sx_c^-$  may also contribute to physiological brain E/I balance. Behaviorally, male  $xCT^{-/-}$  mice demonstrate decreased spatial working memory as determined by reduced alternations in the three-arm spontaneous alternation task compared to wild-type

controls, and similar deficits were found in male and female *SLC7A11<sup>mut/mut</sup>* mice (De Bundel et al 2011, McCullagh & Featherstone 2014). Furthermore, male *SLC7A11<sup>mut/mut</sup>* mice have impaired long-term memory in a hippocampal and amygdala-dependent fear conditioning task as well as in a hippocampal-dependent passive avoidance task (Li et al 2012). Given the memory deficits across several distinct tasks, it is perhaps unsurprising that long-term potentiation at the CA1-Schaeffer collateral synapse is also reduced in male *SLC7A11<sup>mut/mut</sup>* mice (Li et al 2012).

In assays of anxiety, male *xCT<sup>-/-</sup>* mice have a decreased latency to eat in a novelty suppressed eating paradigm and spend an increased amount of time in an open field or in the lighted portion of a light/dark box as compared to wild-type littermates (Bentea et al 2015a). These results suggest that  $Sx_c^-$  increases behavioral anxiety. In addition, *xCT<sup>-/-</sup>* mice demonstrate increased climbing behavior and decreased immobility in the forced swim and tail suspension tests as compared to wild-type littermate controls, suggesting that *xCT<sup>-/-</sup>* mice have less behavioral despair as compared to wild-type controls (Bentea et al 2015a). Of note, motor activity and visual acuity is normal in *xCT<sup>-/-</sup>* and *SLC7A11<sup>mut/mut</sup>* mutants, suggesting that these are unlikely confounds in any of the aforementioned behavioral paradigms (Bentea et al 2015a, McCullagh & Featherstone 2014).

Despite *xCT<sup>-/-</sup>* mice demonstrating enhanced spontaneous and evoked EPSCs at the hippocampal CA3-CA1 synapse (discussed above), De Bundel and colleagues have demonstrated that male *xCT<sup>-/-</sup>* mice have an apparent increase in seizure threshold upon acute stimulation with the chemoconvulsants kainic acid, NMDA, or pilocarpine (De Bundel et al 2011, Williams & Featherstone 2014). Specifically, male *xCT<sup>-/-</sup>* mice

require a higher dose of kainic acid or pilocarpine, delivered via intravenous infusion, to induce seizure activity as compared to wild-type controls (De Bundel et al 2011). Furthermore,  $xCT^{-/-}$  mice have a decreased incidence of mortality and increased latency to convulsive seizure upon administration of a single intraperitoneal dose of NMDA as compared to wild-type mice (De Bundel et al 2011). The increase in seizure threshold in  $xCT^{-/-}$  mice *in vivo* is in stark contrast to their enhanced excitability in *ex vivo* slice (Williams & Featherstone 2014), suggesting a complex regulation of E/I balance by  $Sx_c^-$  *in vivo*. Moreover, these results are also in contrast to findings reported in this dissertation demonstrating a sex-independent decrease in seizure threshold in  $SLC7A11^{sut/sut}$  mice as compared to  $SLC7A11^{+/+}$  sex-matched littermate controls in response to an acute dose of two pharmacologically distinct chemoconvulsants, pentylenetetrazole (Chapter 2, Fig. 2.9) or kainic acid (Chapter 4, Fig. 4.1).

### **1.3 Excitatory/inhibitory (E/I) balance in the brain**

Effective communication between cells in the CNS requires a balance between excitatory and inhibitory neural transmission. This balance is established during development and maintained throughout adulthood (Turrigiano & Nelson 2004). At the network level, the E/I balance refers to the innumerable inhibitory and excitatory neurons that together, maintain a stable circuit [reviewed in (Gao & Penzes 2015, Nelson & Valakh 2015)]. At the cellular level, E/I balance is influenced by the intrinsic membrane excitability and synaptic strength controlling the overall output – or firing probability – of a given neuron (Beck & Yaari 2008, Megias et al 2001, Pratt & Aizenman 2007, Turrigiano et al 1998). Importantly, the physiological E/I balance

provides a stable substrate upon which the information transfer underlying learning and memory formation can occur (Cannon 1932, Zhou & Yu 2018).

Of particular interest to this dissertation is the balance between excitatory glutamatergic and inhibitory GABAergic neural transmission – including the synthesis, release, and uptake of these neurotransmitters, as well as the myriad receptors upon which they exert their influence. Functional alterations at excitatory or inhibitory synapses have been implicated in numerous neurodevelopmental disorders (Gao & Penzes 2015, Nelson & Valakh 2015) and disease states (Foerster et al 2013, Fritschy 2008, Lai et al 2014, Ren et al 2018, Snyder et al 2005), and as such, understanding all factors that contribute to maintenance of E/I balance is integral in developing novel therapeutic targets to provide symptomatic relief. In this section, factors driving normal glutamatergic or GABAergic neural transmission, as well as modulators of E/I balance, including those influenced by  $Sx_c^-$  transport, are discussed.

### ***1.3.1 Inhibitory GABAergic neural transmission***

GABA ( $\gamma$ -aminobutyric acid) is the major inhibitory neurotransmitter in the CNS. Originally classified as a glutamatergic neuromodulator, evidence demonstrating that it is present in large concentrations in the mammalian brain and that iontophoretic application to cortex is sufficient to inhibit cell firing paved the way for its classification as an inhibitory neurotransmitter (Awapara et al 1950, Elliott 1965, Krnjević & Phillis 1963, Krnjević & Whittaker 1965). Additionally, GABA signaling regulates proliferation of neural progenitors and neuronal development (Ge et al 2007, Platel et al 2010).

GABA synthesis and packaging: GABA is predominantly synthesized from glutamate via one of two molecularly distinct enzymes – glutamate decarboxylase 65 (GAD65) or GAD67 – using pyridoxal 5'-phosphate as a cofactor. The subcellular distribution of the two GAD enzymes differs. GAD65 is primarily located in nerve terminals and thus produces GABA for neurotransmission (Martin & Rimvall 1993, Waagepetersen et al 1999). GAD67 is distributed uniformly throughout neurons and provides GABA to fulfill non-neurotransmitter roles such as redox regulation and developmental synaptogenesis (Lamigeon et al 2001, Martin & Rimvall 1993, Waagepetersen et al 1999). Approximately 50% of GAD exists in its inactive, apoenzyme form; this is thought to function as a reserve for when enhanced GABA synthesis is required (Itoh & Uchimura 1981, Miller et al 1980). Alternatively, GABA can be synthesized directly from glutamine derived from the Krebs's cycle via 2-oxoglutarate and glutamate (Waagepetersen et al 1998, Westergaard et al 1995). Following its synthesis, GABA is transported into synaptic vesicles via vesicular GABA transporters (VGATs) in a process dependent on both the membrane potential and the proton gradient (Chaudhry et al 1998, McIntire et al 1997). Interestingly, glycine is a shared substrate for VGATs, and as such, glycine is co-released at certain GABAergic synapses (Wojcik et al 2006).

GABA signaling: Upon depolarization of the GABAergic nerve terminal, a rise in intracellular calcium levels stimulates exocytosis of GABA-containing vesicles (Chen et al 2017). In the synaptic cleft, GABA can activate one of three major GABA receptors (GABARs): the ionotropic GABA<sub>A</sub>R and GABA<sub>C</sub>R as well as the G-protein coupled metabotropic GABA<sub>B</sub>R [for review see (Bormann 2000)].

The GABA<sub>A</sub>R and GABA<sub>C</sub>R are pentameric ligand-gated ion channels that mediate the majority of fast synaptic inhibition [for review see (Bormann 2000)]. As the potassium/chloride (K<sup>+</sup>/Cl<sup>-</sup>) cotransporter (KCC2) maintains relatively low intracellular Cl<sup>-</sup> levels in mature neurons, GABA binding to either ionotropic receptor facilitates a Cl<sup>-</sup> influx and bicarbonate (HCO<sub>3</sub><sup>-</sup>) efflux leading to a net hyperpolarization (Rivera et al 1999). Each receptor is composed of five subunits: there are 18 GABA<sub>A</sub>R subunits ( $\alpha$ 1-6,  $\beta$ 1-4,  $\gamma$ 1-4,  $\delta$ ,  $\epsilon$ ,  $\pi$ , and  $\theta$ ) and three GABA<sub>C</sub>R subunits ( $\rho$ 1-3) [(Bonnert et al 1999, Hedblom & Kirkness 1997) and reviewed in (Macdonald & Olsen 1994, Zhang et al 2001)]. While GABA<sub>A</sub>Rs must contain at least three subunits (including an obligatory  $\alpha$  and  $\beta$  subunit) and are expressed throughout the brain, GABA<sub>C</sub>Rs are only composed of  $\rho$  subunits and are predominantly expressed in the vertebrate retina (Bormann 2000, Bormann & Feigenspan 1995). Despite structural dissimilarities, both GABA<sub>A</sub> and GABA<sub>C</sub> receptors allow for Cl<sup>-</sup> influx upon ligand binding. However, GABA<sub>C</sub>Rs are more sensitive to GABA and have a smaller single channel conductance compared to GABA<sub>A</sub>Rs (major conductance state of 1–5 pS versus  $\approx$ 30 pS) (Chang & Weiss 1999, Karim et al 2013, Wotring et al 1999, Zhang et al 2001). Pharmacologically, GABA<sub>A</sub>Rs are positively modulated by benzodiazepines and barbiturates via binding sites at their subunit interfaces (Chiara et al 2013, Macdonald & Olsen 1994, Pritchett et al 1989). Moreover, GABA<sub>A</sub>Rs are selectively inhibited by the competitive antagonist bicuculline (Andrews & Johnston 1979). In contrast, GABA<sub>C</sub>Rs are benzodiazepine, barbiturate, and bicuculline insensitive (Bormann & Feigenspan 1995).

The GABA<sub>B</sub>R is a G-protein coupled metabotropic receptor capable of modulating synaptic transmission through its intracellular effector systems (Padgett &

Slesinger 2010). Each receptor is a heterodimer consisting of a GABA<sub>B1</sub> subunit – of which there are A and B isoforms – and a GABA<sub>B2</sub> subunit [reviewed in (Heaney & Kinney 2016)]. GABA<sub>B</sub>R activation results in a bicuculline-insensitive GABAergic current that is modulated by the GABA<sub>B</sub>R selective agonist baclofen (Bowery et al 1979). Moreover, GABA<sub>B</sub>R activation is negatively coupled to adenylate cyclase and therefore has an overall inhibitory effect, with presynaptic activation inhibiting neurotransmitter release and postsynaptic activation increasing the K<sup>+</sup> conductance responsible for long-lasting inhibitory postsynaptic potentials (IPSPs) (Kabashima et al 1997, Pérez-Garci et al 2006, Sakaba & Neher 2003).

GABA uptake: GABA released into the synaptic cleft is cleared by GABA transporters expressed on both neurons and astrocytes. There are four known high-affinity GABA transporters, all of which belong to the SLC6 family: GABA transporter 1-3 (GAT1-3), and the betaine-GABA transporter (BGT1) (Guastella et al 1990, Liu et al 1993, Lopez-Corcuera et al 1992, Radian et al 1986, Yamauchi et al 1992). All transporters are Na<sup>+</sup> and Cl<sup>-</sup> coupled, with reported K<sub>m</sub> values of 8 μM (GAT1), 18 μM (GAT2), 0.8 μM (GAT3), and 80 μM (BGT1) (Liu et al 1993, Liu et al 1992, Lopez-Corcuera et al 1992). In the CNS, GAT1 is localized to both neurons and astrocytes whereas GAT3 is selectively expressed in astrocytes (Minelli et al 1995, Minelli et al 1996). In contrast, GAT2 and BGT1 are largely excluded from the brain, except for the encompassing leptomeninges and blood vessels, but are predominantly expressed in the kidney and liver (Zhou et al 2012, Zhou et al 2011). In the brain, GABA taken up by neurons can be directly packaged into vesicles for neurotransmission (Coulter & Eid 2012, Eulenburg & Gomez 2010). Alternatively, in a process known as the GABA

shunt, GABA taken up by neurons or astrocytes can replenish TCA cycle intermediates via its catabolism into succinate by GABA-transaminase (GABA-T) and succinic semialdehyde dehydrogenase (SSADH) (Bak et al 2006, Fonnum & Fyske 2000).

### ***1.3.2 Excitatory glutamatergic neural transmission***

Glutamate is the most abundant excitatory amino acid neurotransmitter in the vertebrate nervous system (Fonnum 1984, Ottersen & Storm-Mathisen 1984). The first evidence of its role as an excitatory neurotransmitter came from the seminal discovery that direct application of glutamate to neural tissue resulted in epileptic seizure activity (Hayashi 1952, Hayashi 1954, Okamoto 1951). Its presence in concentrations three- to four-fold greater than aspartate, glutamine, or taurine – the next three most abundant amino acids in brain – also provided suggestion that it had specialized functions apart from serving as an amino acid building block (McGeer et al 1978). Later work established that glutamate fulfills the criteria for classification as a neurotransmitter: it is localized to nerve terminals, it is released from a neuron upon stimulation, it is capable of activating its cognate receptors, direct application of glutamate mimics neuronal stimulation, and mechanisms exist to rapidly terminate its action (Fonnum 1984, Watkins & Evans 1981). In addition to its role as the major excitatory neurotransmitter in the brain, glutamate is a precursor for GABA and other various Krebs cycle intermediates and it is involved in the regulation of ammonia levels and osmotic balance (McGeer et al 1978, Roberts & Frankel 1950, Weil-Malherbe 1950). Furthermore, glutamate is involved in the synthesis of fatty acids, proteins, and peptides, including glutathione (Meister 1979).

Approximately 80-90% of neurons, and the same proportion of central synapses, are glutamatergic (Braitenberg & Schüz 2013, Ottersen & Storm-Mathisen 1984). Given its ubiquitous CNS localization, it is unsurprising that glutamate signaling is involved in a diverse array of brain functions including sensory transduction, motor coordination, and cognitive processes such as learning and memory [for review see (Hassel & Dingledine 2012)]. However, high fidelity glutamatergic transmission requires a stable substrate – efficient glutamate release and uptake, as well as low ambient extracellular glutamate concentrations – and it follows that alterations in such are associated with neurological disorders and disease states. For example, hypo-glutamatergic signaling is implicated in the cognitive deficits associated with schizophrenia (Moghaddam & Javitt 2012). Moreover, excessive glutamate release and prolonged activation of its receptors can lead to seizures and neuronal cell death via excitotoxicity (Choi 1992, Nadler et al 1978, Olney 1969). Thus, it is essential that the release and uptake of glutamate be tightly regulated.

Glutamate synthesis and packaging: Neurons synthesize glutamate via the hydrolysis of glutamine to glutamate and ammonia, catalyzed by the phosphate-dependent mitochondrial enzyme glutaminase (Errera & Greenstein 1949baker, Laake et al 1999). Alternatively, glutamate can be rapidly transaminated from  $\alpha$ -ketoglutarate, a key intermediate in the Krebs's cycle, via the enzyme glutamate dehydrogenase (Peng et al 1993). Finally, glutamate can be directly transported from the extracellular space into neurons through  $\text{Na}^+$ -dependent EAATs (Danbolt et al 2016). In its final form, glutamate is transported into synaptic vesicles via vesicular glutamate transporters, of which there are three mammalian isoforms (VGLUT1-3 encoded by the genes

SLC17A6-8), to a maximum glutamate concentration of approximately 70-210 mM per vesicle (Burger et al 1989, Omote et al 2011, Riveros et al 1986). Accumulation of glutamate via VGLUTs is chloride-dependent and driven by both the membrane potential and an electrochemical gradient of H<sup>+</sup> ions established by the V-ATPase (Naito & Ueda 1985, Omote et al 2011).

Glutamate release: Upon depolarization of nerve terminals, increasing intracellular calcium levels stimulate vesicular fusion with the presynaptic membrane, allowing for glutamate molecules to be released into the synaptic cleft (Fernandez-Chacon et al 2001, Geppert et al 1994). Though vesicular-mediated neuronal glutamate release mediates the majority of fast excitatory neurotransmission, glutamate can also be released by neurons and/or astrocytes via several other mechanisms. In both cell types, calcium-independent glutamate release can occur via EAAT reversal, especially under pathological conditions such as cerebral ischemia wherein the Na<sup>+</sup> and K<sup>+</sup> gradients across the plasma cell membrane are reduced (Longuemare & Swanson 1995, Nicholls & Attwell 1990, Szatkowski et al 1990). In an attempt to achieve volume homeostasis under hypo-osmotic conditions, neurons and astrocytes may release anions, including glutamate, through volume-regulation anion channels (VRACs) (Kimmelberg et al 1990, Mongin & Orlov 2001). Additionally, astrocytic hemichannels – when left unopposed versus aligned with a hemichannel on a neighboring astrocyte to allow for intercellular gap junction-mediated transport – are independently functional and can efflux glutamate and other amino acids (Ye et al 2003). This mechanism of glutamate release may be functional under conditions of metabolic inhibition when hemichannels appear to open (Contreras et al 2002, John et al 1999), though some

evidence also indicates hemichannels are open physiologically (Bruzzone et al 2001, Kamermans et al 2001, Plotkin & Bellido 2001, Quist et al 2000). Furthermore, P2X<sub>7</sub> receptor-associated ion channels are capable of glutamate efflux upon ligand binding (Duan et al 2003). Moreover, calcium-dependent vesicular glutamate release from astrocytes has been demonstrated, and is supported by evidence that G-protein coupled receptor activation, and the ensuing rise in intracellular calcium levels, culminate in glutamate release (Bezzi et al 1998, Parpura et al 1994). This release mechanism is further substantiated by astrocytic expression of exocytotic machinery including cellubrevin, synaptobrevin II, syntaxin, vesicular soluble N-ethylmaleimide-sensitive factor attachment protein receptors (SNAREs), and VGLUTs (Bezzi et al 2004, Parpura et al 1995, Schwarz et al 2017). However, opposing evidence indicates lack of metabotropic glutamate receptors in adult astrocytes suggesting that vesicular-mediated glutamate release may be a developmental phenomenon (Sun et al 2013). Moreover, astrocyte transcriptome analyses and more recent immunohistochemical data demonstrate a paucity of VGLUT expression (Barres 2008, Cahoy et al 2008, Li et al 2013, Zhang et al 2014) and as such, whether this route of glutamate release exists *in vivo* is hotly debated (for dual perspective reviews see (Fiacco & McCarthy 2018, Savtchouk & Volterra 2018)). Finally, of particular interest to this dissertation, glutamate release occurs via Sx<sub>c</sub><sup>-</sup>-mediated cystine/glutamate exchange (Bannai & Kitamura 1980). Route of release notwithstanding, once released into the synaptic cleft or extracellular space, glutamate binds to its cognate receptors and/or is taken up by EAATs.

Glutamate receptors: Two distinct classes of glutamate receptors exist within the CNS, ionotropic (iGluR) and metabotropic (mGluR) [for reviews see (Niswender & Conn 2010, Traynelis et al 2010)]. Canonical iGluRs are integral membrane cation channels capable of mediating rapid synaptic transmission and can be further classified into three subtypes based upon structure and agonist pharmacology:  $\alpha$ -amino-3-hydroxy-5-methyl-4-isoxazole propionic acid receptors (AMPA receptors), kainic acid receptors (kainate, KARs), and *N*-methyl-D-aspartate receptors (NMDARs) [for review see (Traynelis et al 2010)]. Glutamate delta receptors ( $\delta 1$  and  $\delta 2$ ) are a fourth iGluR subtype, which have been classified as such solely upon sequence homology as they are not gated by glutamate (Lomeli et al 1993, Yamazaki et al 1992). Instead, endogenous ligands for these receptors include D-serine and glycine (Naur et al 2007). The eight mGluR subtypes function as G-protein coupled receptors and can be broadly classified into three subcategories based upon sequence homology, pharmacology, and second messenger systems (Pin & Acher 2002).

Tetrameric AMPARs are assembled using combinations of subunits GluA1-4, with forebrain receptors containing predominantly GluA1/GluA2 and GluA2/GluA3 subunits (Craig et al 1993). Upon glutamate binding, the opening of the ion-channel pore allows for  $\text{Na}^+$  influx and  $\text{K}^+$  efflux, facilitating postsynaptic membrane depolarization with rapid onset and desensitization kinetics (Jones & Westbrook 1996). RNA editing of the GluA2 subunit (Q/R edit) is prevalent in the adult brain, and this feature bestows calcium-impermeability to the pore channel (Greger et al 2003). However, the presence of unedited GluA2 subunits and/or GluA2-lacking AMPARs allow for AMPA-mediated calcium influx; the latter receptors have been demonstrated to

play a role in plasticity, including in the stabilization of long-term potentiation (Plant et al 2006, Yang et al 2010). AMPARs are enriched at glutamatergic synapses, and dendritic spine morphology correlates with the number of synaptic AMPARs (Kasai et al 2003, Matsuzaki et al 2001). Their dynamic trafficking to and from the postsynaptic membrane, often via lateral diffusion from extrasynaptic sites, are key determinants of synaptic strength (Lüscher et al 1999).

KARs are tetrameric receptors composed of a combination of the subunits GluK1-5. These subunits have heterogeneous expression patterns and, although expressed throughout the CNS, predominant localization has been demonstrated in the hippocampus (GluK2, GluK3, GluK4, GluK5) and cerebellum (GluK1, GluK2, GluK5) (Porter et al 1997). In addition to agonist binding, KARs require external monovalent cations and anions at binding sites on the GluK1-5 subunits to allow for pore opening (Bowie 2002, Paternain et al 2003). Similar to AMPARs, Q/R editing within subunits GluK5-6 bestows calcium-impermeability (Köhler et al 1993, Sommer et al 1991). At the postsynaptic membrane, KAR activation enhances excitation, albeit via a slower and smaller excitatory postsynaptic current than AMPAR activation (Castillo et al 1997, Frerking et al 1998). Presynaptically, KAR activation induces depression of inhibition (Rodríguez-Moreno et al 1997, Sloviter & Damiano 1981), thought to occur via a noncanonical metabotropic route of KAR signaling (Rodríguez-Moreno & Lerma 1998). Moreover, presynaptic KAR activation can modulate glutamate release, with facilitation or depression of release at the mossy fiber-CA3 and CA3-CA1 hippocampal synapses dependent upon agonist concentration (Chittajallu et al 1996, Frerking et al 2001, Schmitz et al 2000).

NMDARs are distinct from the aforementioned iGluRs in that they exhibit high calcium permeability (in addition to fluxing  $\text{Na}^+$  and  $\text{K}^+$ ) and mediate the slow component of excitatory synaptic currents, thus allowing for temporal summation (Schiller & Schiller 2001). NMDARs function as coincidence detectors: channel opening is dependent upon the binding of glutamate and glycine along with membrane depolarization to relieve a voltage-dependent magnesium ( $\text{Mg}^{2+}$ ) block (Mayer et al 1984). Much like AMPARs and KARs, the tetrameric assembly of GluN1, GluN2A-D, and/or GluN3A-B subunits dictates their physiology [reviewed in (Sanz-Clemente et al 2013)]. GluN1 and GluN2 subunits are required for receptor function as they contain the glutamate and glycine binding sites, respectively, while receptors containing a GluN3 subunit are calcium impermeable (Kew et al 2000, Laube et al 1997, Matsuda et al 2002, Nishi et al 2001). Given their calcium conductance, NMDARs play a role in the expression of activity-dependent plasticity and multiple lines of evidence suggests that NMDAR trafficking contributes to both Hebbian (long-term potentiation and depression) and homeostatic forms of plasticity as well (Hunt & Castillo 2012, Pérez-Otaño & Ehlers 2005).

G-protein coupled mGluRs are classified into three groups based on agonist pharmacology and intracellular second messenger cascades [for reviews see (Niswender & Conn 2010, Pin & Acher 2002)]. Group I (mGluR 1 and mGluR5) receptors are coupled to phospholipase C and generally lead to increases in protein phosphorylation and activation of calcium binding proteins. Group II (mGluR2 and mGluR3) and III (mGluR4 and mGluR6-8) receptors are negatively coupled to adenylate cyclase, decreasing cAMP production and protein phosphorylation. In the CNS, the

physiological role of mGluR signaling is varied, ranging from positive and negative facilitation of presynaptic neurotransmitter release to inhibition of postsynaptic calcium channels (Pin & Acher 2002).

Glutamate uptake: Extracellular glutamate is taken up by EAATs in an electrogenic process driven by the import of  $3\text{Na}^+$  and  $1\text{H}^+$  coupled to the export of  $1\text{K}^+$  (Barbour et al 1991, Kanner & Schuldiner 1987, Levy et al 1998, Nicholls & Attwell 1990, Zerangue & Kavanaugh 1996). Transport also occurs with an uncoupled  $\text{Cl}^-$  gradient (Bergles et al 2002, Wadiche et al 1995). Rapid glutamate uptake by the EAATs is necessary to prevent overactivation of glutamate receptors and excitotoxic cell death. There are five mammalian EAAT transporters that differ in their cellular and regional distribution, all of which belong to the SLC1 (high affinity glutamate and neutral amino acid) family of transporters (Hediger et al 2013). Found throughout the brain are EAAT1 (GLAST) (Storck et al 1992, Tanaka 1993), localized exclusively on astrocytes (Lehre et al 1995), EAAT2 (GLT-1) (Danbolt et al 1990), localized predominately to astrocytes but also located on some neuronal axon terminals (Chen et al 2004, Furness et al 2008, Zhou et al 2018), and EAAT3 (EAAC1) (Bjørjås et al 1996, Kanai & Hediger 1992), localized to neuronal somata and dendrites (Holmseth et al 2012, Rothstein et al 1994). EAAT4 is found primarily in cerebellar Purkinje cells (Fairman et al 1995, Itoh et al 1997), but also astrocytes (Hu et al 2003), whereas EAAT5 is restricted to retinal bipolar and photoreceptor neurons (Arriza et al 1997). Despite redundant functional activity among the EAATs, the vast majority ( $\approx 95\%$ ) of extracellular glutamate uptake is performed by EAAT2 (Danbolt et al 1992, Haugeto et al 1996, Otis & Kavanaugh 2000). Indeed, genetic deletion of EAAT2 in mice results in spontaneous epileptiform activity

by three weeks of age (Tanaka et al 1997), and spontaneous electrographic seizures and increased mortality have been reported in astrocytic (but not neuronal) EAAT2 conditional knock-out mice (Petr et al 2015). Once taken up into astrocytes, glutamate can be released via one of the aforementioned mechanisms, including  $Sx_c^-$ , or it can be incorporated into proteins, metabolized via the Krebs's cycle, or converted to glutamine via the enzyme glutamine synthetase (Erecińska & Silver 1990, Krebs 1935). The transport of glutamine from astrocytes into neurons via sodium-coupled neutral amino acid transporters (SNATs) or other glutamine transporters is thought to provide the majority of glutamate precursor to neuronal terminals (Jenstad et al 2008, Mackenzie & Erickson 2004, Solbu et al 2010). Together, neuronal glutamate release, its astrocytic uptake and conversion to glutamine, and its subsequent transport to neurons for glutamate or GABA synthesis is referred to as the glutamine-glutamate (GABA) shuttle (Hertz 2013).

### ***1.3.3 Modulators of E/I Balance***

Other than fast inhibitory or excitatory synaptic transmission, a comprehensive understanding of mechanisms underlying brain E/I balance includes the effects exerted by neuromodulators. These include substances such as brain derived neurotrophic factor (BDNF) and adenosine, as well as a cell type of particular interest to this dissertation, astrocytes. Interestingly, astrocytes can release soluble factors, such as glypicans, tumor necrosis factor- $\alpha$  (TNF $\alpha$ ), and secreted protein acidic and rich in cysteine (SPARC), that influence synaptogenesis and synaptic activity (Allen et al 2012, Jones et al 2011, Stellwagen & Malenka 2006). Moreover, the glutamate-glutamine

cycle, maintained by astrocytes, controls synaptic strength during period of intense neuronal activity (Tani et al 2014). Of interest to this dissertation is how the intracellular/extracellular redox environment and ambient extracellular glutamate levels – two parameters maintained in part by astrocytes and influenced by  $Sx_c^-$  signaling – contribute to E/I balance.

### *1.3.3.1 Redox status*

Numerous lines of evidence suggest that redox status influences the E/I balance. For instance, a redox imbalance is associated with impaired neuronal synaptic plasticity (Almaguer-Melian et al 2000, Robillard et al 2011), with effects of such on seizure activity reported (Jiang et al 2000, Liang & Patel 2004). However, the exact mechanism by which redox signaling influences E/I balance is unclear, with reports of increased (Liang & Patel 2004) or decreased (Jiang et al 2000) seizure activity in mice under oxidative stress. Moreover, compounds with antioxidant properties (vitamin C, superoxide dismutase [SOD], melatonin, and N-acetylcysteine) have been demonstrated to reduce seizures and seizure-induced cell death in several animal models of epilepsy (MacGregor et al 1996, Rong et al 1999, Tan et al 1998, Zaeri 2015). Interestingly, both glutamate transporters and the NMDAR possess redox-sensing properties that regulate their activity (Aizenman et al 1989, Köhr et al 1994, Sullivan et al 1994, Trotti et al 1997), suggesting that a redox imbalance can modulate E/I balance through influencing glutamatergic neural transmission.

### 1.3.3.2 Ambient extracellular glutamate

Despite the efficient glutamate uptake mechanisms described earlier, there is a pool of ambient extracellular glutamate that bathes the CNS *in vivo*. Estimates of the ambient extracellular glutamate concentration range from 25-90 nM as determined by electrophysiological measurement of tonic NMDAR activity in acute brain slices (Benveniste et al 1984, Cavelier & Attwell 2005, Herman & Jahr 2007, Meur et al 2007) to 0.2-35  $\mu$ M as measured by *in vivo* microdialysis (Baker et al 2003, Dash et al 2009, De Bundel et al 2011, Massie et al 2011b). Some reports postulate that the discrepancy in ambient glutamate concentrations could reflect compartmentalization within distinct synaptic (nM) and extrasynaptic ( $\mu$ M) glutamate compartments (Baker et al 2002, Moussawi et al 2011). Another possibility for the discordant measurements in ambient glutamate is that *in vivo* microdialysis studies are typically performed in adult mice whereas acute slice experiments are performed using young rodents (postnatal day 11-19), a point in development when glutamate transporters, including  $Sx_c^-$ , are not yet fully expressed (Kugler & Schleyer 2004, La Bella et al 2007). However, the two aforementioned theories were recently refuted by work demonstrating that ambient glutamate levels in acute brain slices are  $\approx 25$  nM *throughout* the brain in both young (postnatal day 15-22) and old (8-12 week old) rats, indicating a distinct lack of compartmentalization and age-related differences in rat (Chiu & Jahr 2017). Finally, micromolar glutamate levels as measured by *in vivo* microdialysis could be an artifact of tissue damage inflicted by the sampling probe, thus rendering the adjacent neuropil metabolically impaired (Sun et al 2014).

Despite conflicting reports over the precise concentration of extracellular glutamate, evidence suggests that ambient levels are sufficient to influence E/I balance. For instance, tonic activation of NMDARs by glutamate of non-vesicular origin ( $\text{Ca}^{2+}$ -independent, tetrodotoxin-insensitive) regulates the intrinsic excitability and synchronization of hippocampal pyramidal and granule cells (Angulo et al 2004, Cavelier & Attwell 2005, Dalby & Mody 2003, Jabaudon et al 1999, Meur et al 2007, Sah et al 1989). Moreover, tonic exposure to micromolar levels of glutamate has been demonstrated to cause steady-state glutamate receptor desensitization and suppression of synaptic strength (Augustin et al 2007, Williams & Featherstone 2014, Zorumski et al 1996). Other evidence points to a role for ambient glutamate in depolarization induced suppression of inhibition (DSI) of inhibitory interneurons through its activation of pyramidal cell mGluRs in the hippocampus (Varma et al 2001). Finally, a developmental role for ambient glutamate in E/I circuit formation has been suggested, with reports indicating it can regulate cellular differentiation and migration (LoTurco et al 1991, LoTurco et al 1995, Manent et al 2005, Nguyen et al 2001).

#### **1.3.4 Use of chemoconvulsants to investigate E/I balance *in vivo***

Experimentally, baseline E/I balance can be measured using brain slice or *in vivo* electrophysiological recordings. Alternatively, the use of pharmacological agents to stimulate or inhibit excitatory and/or inhibitory signaling can be used to uncover an E/I imbalance that may not be apparent physiologically. Pertinent to the studies performed in this dissertation, the chemoconvulsants pentylenetetrazole (PTZ) and kainic acid (KA) will be discussed. As potent chemoconvulsants, PTZ and KA are capable of eliciting

seizures, which is a brain state characterized by abnormally excessive or synchronous neuronal activity (Fisher et al 2005). The aberrant electrical activity induced by a seizure can be recorded via electroencephalography; it also manifests as behavioral motor changes ranging from immobility to generalized convulsive seizures involving clonic limb movements. Thus, by using frank motor seizures as a behavioral readout, chemoconvulsant-induced brain excitation is readily observable.

#### *1.3.4.1 Pentylentetrazole (PTZ)*

PTZ was first characterized as an inhibitor of GABA<sub>A</sub>Rs in 1978 (Macdonald & Barker 1978). Several years later, radioligand studies determined its site of action to be at the picrotoxin binding site within the GABA<sub>A</sub>R channel pore (Ramanjaneyulu & Ticku 1984, Squires et al 1984). A more recent report by Huang and colleagues indicated that PTZ and picrotoxin share common but not identical domains of action, as the PTZ antagonized-GABA<sub>A</sub>R current occurs exclusively through competitive inhibition whereas picrotoxin displays both non-competitive and competitive inhibition of GABA<sub>A</sub>Rs (Huang et al 2001). Following its synthesis in 1924, PTZ was initially used as a cardiovascular and respiratory stimulant (Haury 1939). In a line of investigation stemming from his postmortem neuropathological observations of decreased gliosis in schizophrenic tissue versus enhanced gliosis in epileptic tissue, Meduna began using PTZ in 1934 as a therapeutic treatment to induce epileptic activity in schizophrenic individuals in an attempt to stimulate gliosis (Meduna 1932, Meduna 1935). Eventually, PTZ was replaced with electroconvulsive therapy as the therapeutic stimulant of choice in mood disorders and schizophrenia (Bini 1938).

PTZ administration in laboratory animals is traditionally used to experimentally test the efficacy of anti-seizure drugs in response to seizure activity (Swinyard 1949). Alternatively, it can be used in rodents to explore their seizure threshold, or the innate balance between excitation and inhibition that influences seizure susceptibility (Steppuhn & Turski 1993). Finally, PTZ can be used as a chemical kindling agent to model epileptogenesis – which is the process by which a normal brain network develops spontaneous recurrent seizures (i.e. epilepsy) over time. The kindling phenomenon occurs via a gradual sensitization of neuronal circuitry to repeated application of a low intensity stimulus (Goddard 1967). A similar period of sensitization is thought to occur during the latent period of acquired epilepsies, which are a group of diseases characterized by spontaneous seizures resulting from an antecedent CNS injury and ensuing latent, seizure-free period (Braunwald et al 2001, Victor & Ropper 2002). Thus, kindling serves as a model of acquired epilepsies, and understanding the cellular and molecular mechanisms facilitating this period of sensitization is integral in developing therapeutic targets to thwart their progression (Jensen 2009). Moreover, given that kindling induces synaptic changes over time it is, at its core, a plasticity model. In fact, kindling shares common mechanisms with long-term potentiation (LTP) (Cain 1989, Goddard & Douglas 1975) and as such, it can be used to study how E/I balance evolves during plastic sensitization of neuronal circuitry.

Though strain differences exist with regards to seizure presentation, in general, within tens of seconds of receiving a systemic dose of PTZ rodents will socially isolate themselves, becoming distinctly hypomobile and unresponsive (Kosobud et al 1992). These seizures can evolve into myoclonic muscle jerks, indicative of increased

synchronous neuronal activity in the motor cortex. Depending on the dose of PTZ (sub-convulsive vs. convulsive), seizure severity can further progress into a generalized convulsive episode involving forelimb and/or hindlimb clonus. This progression of seizure activity – from behavioral immobility and facial automatisms, to forelimb clonic movements and generalized convulsions – was first characterized by Ronald Racine (Racine 1972).

In the seminal kindling studies performed by Goddard, the stimulus was a sub-convulsive threshold electrical current, delivered daily via depth electrodes implanted in rat amygdala (Goddard 1967). Several years later, several studies pioneered the use of PTZ as a chemical kindling agent (Ito et al 1977, Mason & Cooper 1972). In this model, a low dose of PTZ is administered daily via systemic injections. Over time, an initially sub-convulsant dose will evoke behavioral convulsions, at which point an animal is considered to be “kindled” (Dennison et al 1995, Wada et al 1974), an effect generally viewed as being permanent. It should be noted that the kindling phenomenon is not specific to rodents, rather, it has been demonstrated in every species tested, from frog to humans, where a similar seizure progression was observed in response to brain tumors (McNamara 1986, Morrell 1985).

#### 1.3.4.2 Kainic Acid (KA)

The excitatory agent KA was first isolated by Murakami and colleagues from the red seaweed *Digenea simplex* (Murakami et al 1953). Soon after, it was found that microiontophoretic administration to cortical neurons resulted in prolonged spike discharges (Shinozaki 1978, Shinozaki & Konishi 1970), followed next by the

observation that parenteral KA delivery resulted in excitotoxic, depolarization-induced cell death (Olney et al 1974). In its seminal use as a chemoconvulsant, Lagowska and Ben-Ari discovered that KA administration in the amygdala produced prolonged, recurrent convulsive seizures (status epilepticus), heralding its use in epilepsy research (Ben-Ari & Lagowska 1978). Indeed, KA induces excitatory activity as it exhibits affinity for both AMPARs as well as its own cognate receptors, bindings to KARs containing the GluK1-2 and GluK5-7 subunits with high-affinity (Vincent & Mulle 2009). Within minutes of systemic KA administration, animals become immobile and/or hypermobile – including unilateral rotations and/or pacing – which can further progress to displays of myoclonic twitching, kyphotic rearing, and paw clonus associated with rearing [personal observations and (Ben-Ari 2012, McKhann II et al 2003)]. Depending on the dose, these seizures can evolve into generalized convulsions and “popcorn” like violent jumping that in some instances culminates in death [personal observations and (Ben-Ari 2012, McKhann II et al 2003)]. Following KA administration, early activation of the hippocampus and amygdala, two brain regions with a particularly low seizure threshold, is observed via EEG recording (Ben-Ari 2012). Postmortem analysis of KA-treated animals reveals extensive cell loss in hippocampal CA3, a region particularly vulnerable to KA-induced excitation, in part, due to a high density of KARs and excitatory recurrent collaterals that, once synchronous, propagate to other structures within the limbic system and brain (Ben-Ari 2012, Ben-Ari & Cossart 2000, Miles & Wong 1983, Robinson & Deadwyler 1981, Vincent & Mulle 2009, Westbrook & Lothman 1983). Finally, the KA-induced model of status epilepticus represents a model of acquired

epilepsy as animals can develop spontaneous seizures several weeks to months following the initiation of seizure activity (Ben-Ari 2012).

### **1.3.5 Current need for understanding E/I balance**

An E/I imbalance has been implicated in numerous neurological disorders and disease states. For instance, dysfunction of GABAergic signaling, glutamatergic signaling, or both has been implicated in the etiology of autism spectrum disorders (ASD), anxiety, depression, intellectual disability, cerebral ischemia, traumatic brain injury, schizophrenia, and epilepsy (Coghlan et al 2012, Luscher & Fuchs 2015, Meldrum 1994, Moghaddam & Javitt 2012, Olsen & Avoli 1997). This is exemplified by ASDs and schizophrenia which, despite varied genetic etiologies, both present with similar E/I deficits including NMDAR hypofunction (Akbarian et al 1996, Blundell et al 2010, Duffney et al 2013, Gao & Penzes 2015, Maliszewska-Cyna et al 2010, Morris et al 2005). In fact, an emerging hypothesis is that a shared pathophysiological E/I imbalance underlies similar social and cognitive behavioral phenotypes in ASD and schizophrenia (Gao & Penzes 2015). Furthermore, while dozens of disease associated genes have been implicated in epilepsy (Poduri & Lowenstein 2011), behavioral presentation of spontaneous seizures – the hallmark of epilepsy diseases – are thought to be a result of commonalities in GABAergic hypofunction and/or glutamatergic hyperfunction (Bradford 1995). Given the prevalence of disorders and disease states associated with an E/I imbalance, it is necessary to fully understand all cellular and molecular processes that underlie normal, physiological E/I transmission in order to

develop novel therapeutic options to provide individuals with an E/I imbalance symptomatic relief.

## 1.4 Specific Aims

Numerous studies demonstrate that  $Sx_c^-$  is an important contributor to the ambient extracellular glutamate levels that bathe the central nervous system *in vivo* (Augustin et al 2007, Baker et al 2002, Bannai 1986, De Bundel et al 2011, Massie et al 2011a, Melendez et al 2005). Moreover,  $Sx_c^-$ -mediated cystine import provides cells with the rate-limiting substrate (cysteine) of the major cellular antioxidant glutathione; it also forms a redox couple on its own (Banjac et al 2008, Dringen 2000). Given that glutamate signaling and cellular redox status both influence neuronal excitability, the objective of this dissertation was to determine whether endogenous  $Sx_c^-$  signaling contributes to E/I balance *in vivo* and if so, to investigate the mechanism(s) underlying its contribution.

### 1.4.1 Specific Aim 1

**Experiments were designed to determine whether  $Sx_c^-$  contributes to the E/I balance *in vivo* using the acute-PTZ seizure threshold test (Chapter 2).** Female and male mice that harbor a spontaneous mutation in  $Sx_c^-$  (*SLC7A11<sup>sut/sut</sup>* mice) were used to assess the contribution of endogenous  $Sx_c^-$  signaling in acute seizures induced indirectly by disinhibition achieved via administration of the GABA<sub>A</sub> receptor antagonist PTZ. Moreover, experiments in this aim characterized naïve *SLC7A11<sup>sut/sut</sup>* mice by exploring the extent to which loss of  $Sx_c^-$  affected brain morphometry at the gross and cellular level.

### **1.4.2 Specific Aim 2**

**Experiments were designed to determine whether  $Sx_c^-$  signaling affects synaptic plasticity assessed using the PTZ-kindling model of epileptogenesis (Chapter 3).**

Whether endogenous  $Sx_c^-$  signaling contributed to epileptogenesis was assessed by comparing PTZ-kindling acquisition between male *SLC7A11<sup>sut/sut</sup>* and *SLC7A11<sup>+/+</sup>* littermates. Furthermore, experiments in this aim addressed whether observed changes in PTZ-kindling were associated with morphological changes implicated in epileptogenesis, with changes in brain redox status, and/or with changes in plasma membrane protein expression.

### **1.4.3 Specific Aim 3**

**Experiments were designed to determine whether  $Sx_c^-$  signaling regulates E/I balance using both the acute-KA seizure threshold test and the elevated KA dosing model of status epilepticus (Chapter 4).** To explore whether results found in chapters two and/or three were model-dependent, this specific aim used a pharmacologically distinct chemoconvulsant, KA, to directly elicit excitation *in vivo* in two different dosing paradigms.

**Aim 3.1:** Female and male *SLC7A11<sup>sut/sut</sup>* and *SLC7A11<sup>+/+</sup>* littermates were used to assess the contribution of endogenous  $Sx_c^-$  signaling to acute seizures induced by KA.

**Aim 3.2:** Whether endogenous  $Sx_c^-$  signaling contributed to the incidence of status epilepticus elicited using an elevated KA dosing paradigm was assessed using female and male *SLC7A11<sup>sut/sut</sup>* and *SLC7A11<sup>+/+</sup>* littermates. Furthermore,

the contribution of endogenous  $Sx_c^-$  signaling to repeated KA dosing-induced cell death and KA-mediated changes in glutamate or GABA receptor plasma membrane protein expression levels was investigated.

## 1.5 Significance

A variety of neurological disorders and disease states are afflicted by an E/I imbalance (Section 1.3.5). In order to develop therapeutic targets for disease states resulting from an E/I imbalance, including epilepsy, we must first fully understand the cellular and molecular processes that underlie normal, physiological transmission. Towards this end, the results presented herein provide the first evidence that physiological  $Sx_c^-$  function maintains E/I balance *in vivo* in both female and male mice. Additionally, evidence is presented implicating  $Sx_c^-$  in epileptogenesis. As such, the work presented in this thesis may pave the way for the development of therapeutic targets to combat an E/I imbalance.

**Chapter 2: Sex-dependent alterations in neuronal morphometry occur in association with altered E/I balance in system  $x_c^-$  null mice**

## 2.1 Summary

Despite evidence that the cystine/glutamate antiporter  $Sx_c^-$  contributes to ambient extracellular glutamate levels and redox status, its contribution to physiological brain function *in vivo* remains incompletely defined. As such, the present study investigated whether and how  $Sx_c^-$  contributes to morphological parameters implicated in E/I balance, as well as, whether it contributes to acute seizure activity elicited by the chemoconvulsant PTZ. Gross brain and cellular morphology were explored using thionin or Golgi-Cox staining, respectively, in female and male  $SLC7A11^{+/+}$  and  $SLC7A11^{sut/sut}$  mice. Furthermore, littermate mice were administered an acute dose of PTZ (i.p.) and seizure severity was scored using a five-point behavioral scale. Our results demonstrate that loss of  $Sx_c^-$  signaling results in sex-dependent brain morphological alterations at the gross, cellular, and sub-cellular level. Specifically, female  $SLC7A11^{sut/sut}$  mice have decreased corpus callosum thickness, soma size, and dendritic spine head widths as compared to  $SLC7A11^{+/+}$  sex-matched littermate controls. Conversely, male  $SLC7A11^{sut/sut}$  mice have enhanced dendritic complexity and dendritic spine head widths as compared to  $SLC7A11^{+/+}$  sex-matched littermate controls. Interestingly, these sex-dependent morphological alterations occur in association with a sex-independent enhancement of neuronal excitability, exemplified by a decreased convulsive seizure threshold upon administration of an acute dose of PTZ. This study provides the first evidence that  $Sx_c^-$  signaling regulates brain morphology in a sex-dependent manner, and that loss of  $Sx_c^-$  disrupts E/I balance in the acute PTZ seizure threshold test.

## 2.2 Introduction

System  $x_c^-$  ( $Sx_c^-$ ) is an amino acid antiporter that couples the import of L-cystine (CySS) with the export of L-glutamate (Glu) with 1:1 stoichiometry (Bannai 1986, Bannai & Kitamura 1980).  $Sx_c^-$  is a heterodimer composed of a light chain (xCT, encoded by *SLC7A11*) that confers substrate specificity linked via a disulfide bridge to a heavy chain (4f2hc or CD98, encoded by *SLC3A2*) that traffics xCT to the plasma membrane (Bassi et al 2001, Sato et al 1999, Verrey et al 2004). Within the central nervous system (CNS), transcriptome and immunohistochemical analyses conclude that  $Sx_c^-$  is predominantly localized to astrocytes (Ottestad-Hansen et al 2018, Pow 2001, Zhang et al 2014).

Evidence from xCT mutants indicates that  $Sx_c^-$ -mediated glutamate release accounts for >50% of the ambient extracellular glutamate pool that bathes the CNS *in vivo* (Augustin et al 2007, De Bundel et al 2011). This pool of glutamate is largely regulated by glial transporters, and multiple studies suggest it plays a role in maintaining physiological excitatory/inhibitory (E/I) balance. For example, glial-derived ambient glutamate can modulate neuronal Kv2.1 channels, whose somatodendritic location and delayed-rectifier  $K^+$  current exert a strong influence on action potential initiation (Mulholland et al 2008, Murakoshi & Trimmer 1999). Moreover, tonic activation of NMDA receptors by ambient glutamate regulates the intrinsic excitability and synchronization of hippocampal pyramidal and granule cells (Angulo et al 2004, Cavelier et al 2005, Dalby & Mody 2003, Meur et al 2007, Sah et al 1989). Other evidence points to a role for ambient glutamate in depolarization induced suppression of inhibition (DSI) of inhibitory interneurons through its activation of pyramidal cell

metabotropic glutamate receptors (mGluRs) in the hippocampus (Varma et al 2001). Pertinently, studies performed in xCT mutants have demonstrated that genetic deletion of xCT results in increased (200-300%) postsynaptic glutamate receptors in *Drosophila*, and male transgenic xCT null mice have enhanced AMPA receptor surface expression and larger evoked and spontaneous EPSCs in *ex vivo* slice (Augustin et al 2007, Williams & Featherstone 2014). Although the magnitude of EPSCs is positively correlated with morphological parameters, such as dendritic complexity (Klenowski et al 2016) and dendritic spine geometry (Matsuzaki et al 2001), whether mice null for  $Sx_c^-$  have cellular morphological alterations is not known.

$Sx_c^-$  also contributes to the intracellular/extracellular redox homeostasis; CySS import through  $Sx_c^-$  is necessary for the synthesis and maintenance of the cellular antioxidant glutathione (GSH) and contributes to the cysteine/cystine (Cys/CySS) redox cycle across the cell plasma membrane (Banjac et al 2008, Sato et al 2005). Interestingly, cellular redox status influences the E/I balance in part because glutamate receptors (NMDA) and transporters are susceptible to redox modification; disulfide reduction potentiates NMDA mediated currents and increases glutamate uptake whereas thiol oxidation does the opposite (Aizenman et al 1989, Köhr et al 1994, Sullivan et al 1994, Trotti et al 1997). Additionally, GSH participates in signal transduction and regulates gene expression, cellular metabolism, and cell proliferation (Lu 2009, Wu et al 2004). Moreover, GSH deficiency in excitatory amino acid transporter 3 (EAAT3/EAAC1) null mice (Aoyama et al 2006), as well as pharmacologically induced GSH deficiency in rats (Jain et al 1991), occurs in association with brain tissue atrophy, suggesting that decreased GSH levels induces

neurodegeneration. However, exactly how redox balance influences excitability *in vivo* appears to be complex; mice deficient in glutathione peroxidase, with elevated brain oxidative stress levels, display less seizure activity following KA administration whereas manganese superoxide dismutase (SOD<sup>+/-</sup>) mice with chronic mitochondrial oxidative stress have increased seizure severity (Jiang et al 2000, Liang & Patel 2004). Pertinently, male and female transgenic xCT null mice have elevated levels of plasma CySS (Sato et al 2005). However, male transgenic xCT null mice have normal levels of hippocampal GSH and are resistant to seizures elicited by intravenous infusion of three pharmacologically distinct chemoconvulsant – pilocarpine, NMDA, or KA (De Bundel et al 2011).

Taking an *in vivo* approach, we investigated whether female and male Sx<sub>c</sub><sup>-</sup> null (*SLC7A11<sup>sut/sut</sup>*; *sut/sut*) mice have alterations in brain excitability as compared to wild-type littermate control mice. Given that changes in synaptic efficacy and redox balance are associated with changes in brain morphology, we investigated whether alterations in such occurred in *SLC7A11<sup>sut/sut</sup>* mice. Herein, we demonstrate that sex-dependent changes in neuronal morphology occur in association with a sex-independent increase in susceptibility to PTZ-evoked convulsive seizures in *SLC7A11<sup>sut/sut</sup>* mice. These results indicate that Sx<sub>c</sub><sup>-</sup> signaling contributes to the endogenous network activity that maintains E/I balance *in vivo*.

## 2.3 Materials and Methods

### 2.3.1 Animals

Mice were bred and maintained in the AALAC accredited Laboratory Animal Resource facility of Syracuse University on a 12 hr light/dark schedule (7am/7pm). Standard mouse chow and water were provided *ad libitum*. Wild-type ( $SLC7A11^{+/+}$ ) and xCT mutant ( $SLC7A11^{sut/sut}$ ) littermates for studies were derived from heterozygous ( $SLC7A11^{+/sut}$ ) breeding units (F1) that were obtained by crossing  $SLC7A11^{sut/sut}$  male mice [Jackson Laboratories (JAX) Stock #001310] with  $SLC7A11^{+/+}$  female C3H/HeSnJ mice (JAX, Stock #000661). F2  $SLC7A11^{+/sut}$  progeny were also used as breeding units for studies. Genotyping was performed via PCR analysis of tail genomic DNA samples:  $+/+$  primers, 5'- GAA GTG CTC CGT GAA GAA GG -3' (forward), 5'- ATC TCA ATC CTG GGC AGA TG -3' (reverse);  $sut/sut$  primers, 5'- CCA CTG TTG TAG GTC AGC TTA GG -3' (forward), 5'- CAG GAC CTG TGA ATA TGA TAG GG -3' (reverse). Mice were segregated by sex at weaning and  $SLC7A11^{+/+}$  and  $SLC7A11^{sut/sut}$  housed two to four per cage. Experiments were carried out on female and male mice 8-12 weeks of age in accordance with the National Institutes of Health guidelines for the use of experimental animals as approved by the Institutional Animal Care and Use Committee of Syracuse University. These breeding and housing strategies were employed to control for environmental differences, genetic background influences, and genetic drift (Barnwell et al 2009, Pick & Little 1965).

### **2.3.2 Gross Brain Morphology Measurements**

Brains were harvested from naïve 12 week old *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* littermates and snap-frozen on dry ice in Optimal Cutting Temperature (O.C.T) compound (Tissue-Tek, Torrance, CA). Frozen sections (coronal, 40  $\mu\text{m}$ ) were cut on a cryostat at 80  $\mu\text{m}$  intervals, mounted on SuperFrost Plus slides (Fisher Scientific, Houston, TX), and thionin-stained as we previously describe (Chowdhury et al 2018). ImageJ Software (version 1.47v or 1.51n; National Institutes of Health, Bethesda, MD, RRID: SCR\_003070) was used to make gross brain morphological measurements on scanned images (Epson 3170; 720 dpi) of slices at +1.1, -0.1, -0.94, -1.46, and -2.54 mm relative to bregma by three individuals blind to genotype. Mean cortical width was obtained by averaging six non-overlapping, straight tool measurements taken from the apex of the corpus callosum to the pial layer in the somatosensory cortex (3 each bilaterally). Mean corpus callosum width was obtained by averaging three non-overlapping, straight tool measurements taken from the base to the apex of the corpus callosum at the midline. Mean ventricular, striatal, hemispheric, and corpus callosum areas were determined by averaging user-defined pixel volumes using the free hand tool taken of the respective regions measured three times bilaterally (six in total) or three times total for structures decussating the midline (corpus callosum). In all cases, data are expressed as the mean  $\pm$  SEM of measurements obtained from animals in the respective genotype derived from the mean calculated from three individual raters blind to experimental conditions.

### **2.3.3 Cellular Morphological Measurements**

#### *2.3.3.1. Golgi-Cox Staining*

Brains from naïve *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* littermates were Golgi-Cox stained using the FD Rapid Golgi Stain Kit (FD Neuro Technologies, Inc., Baltimore, MD) as per manufacturer's instructions. Following removal from the cranium, brains were immediately rinsed in deionized (DI) water, placed in a proprietary impregnation solution (Solution A plus B) containing potassium dichromate, potassium chromate, and mercuric chloride, and stored at room temperature for 14 days in the dark. Brains were then transferred to a sucrose solution (Solution C) for 3 days followed by rapid freezing on dry ice. Frozen brain were cut serially ( $\approx +2.46 - -2.30$  mm posterior to bregma) into 140  $\mu$ m coronal sections, mounted on gelatin-coated slides (FD Neuro Technologies, Inc., Baltimore, MD), air dried at room temperature for 2 days in the dark. Sections were Golgi-Cox stained as per manufacturer's instructions (FD Rapid Golgi Stain Kit). Briefly, sections were initially rinsed 2x with DI water (4 min each) then placed in a solution containing silver nitrate (Solution D plus E) for 10 min. Slides were rinsed in DI water 2x for 4 min each followed by serial dehydration in absolute ethanol (50%, 75%, 95%, 100%, 100%, 100%, 100%; 4 min each). Ethanol was cleared with xylene (3x for 4 min each), after which coverslips were mounted using Permount mounting media.

#### *2.3.3.2 Dendritic Morphology and Soma Area Analysis*

Photomicrographs of Golgi-Cox stained layer V pyramidal cells in the primary motor cortex (PM1) were obtained with a Nikon eclipse Ni-U upright microscope with motorized stage at 20x magnification. Neurons whose cell body and dendrites were completely impregnated and visible within the plane(s) of focus were selected for

analysis. Neurons were reconstructed with Adobe Illustrator. The complexity of dendritic arborization in reconstructed neuronal drawings was quantified (Image J) using Sholl analysis as described (Sholl 1953). Briefly, the number of dendrites intersecting concentric circles of a gradually increasing radius from the centroid of the soma were calculated. The soma cross-sectional area was quantified using the polygon tool in Image J. The number and length of primary, secondary, tertiary, apical, and basal dendrites were also determined using Neuron J. Experimenters blind to genotype performed the image acquisition and analyses. Six to 11 neurons from 3-5 mice/genotype/sex were analyzed; data are expressed as the mean  $\pm$  SEM of all measurements obtained.

#### *2.3.3.3 Spine Morphometric and Density Analysis:*

Photomicrographs of Golgi-Cox stained secondary apical dendrites on layer V pyramidal cells in the PM1 were obtained with a Nikon eclipse Ni-U upright microscope with motorized stage at 60x magnification. Neurons whose cell body and dendrites were completely impregnated and were visible within the plane(s) of focus were selected for analysis. Spine morphometric analysis was carried out as described (Risher et al 2014). In brief, Z-stack sections were analyzed using RECONSTRUCT software by measuring the length and head width of all protrusions (spines) along the dendritic segment of interest. The spine density was determined by calculating the number of protrusions/ $\mu\text{m}$  of dendrite. The length-to-width ratios (LWR) of individual spines were calculated in Microsoft Excel and used for hierarchical classification into the following categories: branched (entered manually by experimenter), filopodia (length  $> 2\mu\text{m}$ ), mushroom (width  $> 0.6\mu\text{m}$ ), long thin (length  $> 1\mu\text{m}$ ), thin (LWR  $> 1$ ), and stubby (LWR  $\leq 1$ ). All

image acquisition and analyses were performed by experimenters blinded to genotype. Eight-nine neurons from three mice/genotype/sex were analyzed; data are expressed as the mean  $\pm$  SEM of all measurements obtained.

### **2.3.4 PTZ dosing paradigm**

Five days prior to each study, *SLC7A11<sup>+/+</sup>* or *SLC7A11<sup>sut/sut</sup>* mice were acclimated to handling by performing mock daily intraperitoneal (i.p.) injections which consisted of inverting the mouse and rubbing its abdomen. Prior to each experiment, mice were brought into the procedure room, weighed, and allowed to acclimatize for at least one hour. PTZ (Sigma Chemical Co., St. Louis, MO) was dissolved in saline, filter sterilized, and administered i.p. in a volume of 10 ml/kg body weight. Mice were injected with a single dose of PTZ. Doses were chosen following initial dose ranging studies in female and male *SLC7A11<sup>+/+</sup>* or *SLC7A11<sup>sut/sut</sup>* mice to determine the PTZ seizure threshold for each strain (Supplementary Fig. S1) (Kosobud et al 1992). Following each injection, mice were observed for acute behavioral seizures over the next 30 min. The time and severity of behavioral seizures (see Table 2.1 below) were scored and recorded for each mouse by an observer blinded to genotype to ensure unbiased scoring. The percentage of animals exhibiting convulsive seizures was determined by dividing the number of animals with a maximum seizure score of 3 or 4 by the total number of animals injected.

### **2.3.5 Statistical analysis**

All statistical analyses were performed using GraphPad Prism (Version 6.0.1, Graphpad Software, Inc., La Jolla, CA). Brain morphological parameters, including areas, lengths, and widths, were compared using two-way ANOVA. Prior to parametric analysis, count or percentage data were log ( $y = \log(y)$ ) or arcsine ( $y = \arcsine[\sqrt{y/100}]$ ) transformed, respectively. Seizure severity was compared using a Mann-Whitney U test, whereas proportions indicating the percent of mice convulsing were compared using a Fisher's exact test. In all cases, significance was set at  $p < 0.05$ .

***Table 2.1: Descriptive PTZ-induced Seizure Scoring System***

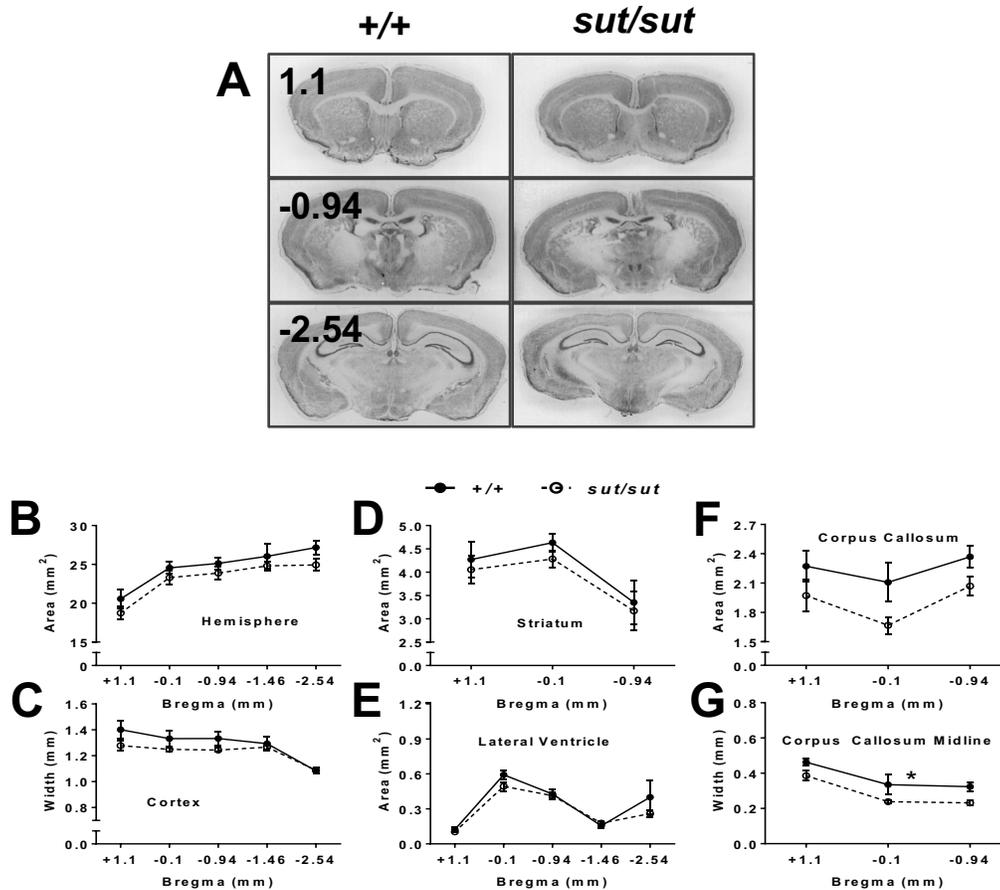

<b>Seizure Score</b>	<b>Abbreviated Description</b>	<b>Detailed Description</b>
<b>0</b>	Normal behavior	Frequent ambulation/exploration, sniffing, rearing, peer interactions, grooming, eating, digging, climbing are common.
<b>1</b>	Hypomobility and hypoactivity	Mice will socially isolate self and disregard peers; body will be positioned close to bottom of cage. The overall behavioral picture will be dominated by bouts (>10 sec in duration) of staring and motionlessness that may be interrupted by brief sniffing or ambulation.
<b>2</b>	Repeated myoclonus	Animal exhibits at least two isolated myoclonic seizures typically involving axial muscles, commonly seen as neck flexion. Straub tail (dorsiflexion) is also common, as is an increase in locomotor activity (compared to score 1).
<b>3</b>	Convulsive seizure with intact righting reflex	Clonic seizures involve forelimbs and neck while the animal assumes an upright posture using hind limbs to support body weight.
<b>4</b>	Convulsive seizure with loss of righting reflex	Clonic seizures involve both forelimbs and hind limbs preventing the maintenance of upright posture. Infrequently, these seizures can be associated with violent running and jumping episodes and tonic hind limb extension.

Table adapted from descriptions in (Ferraro et al 1999, Pitkanen 2006, Racine 1972).

## 2.4 Results

### ***Gross morphometric analysis of $SLC7A11^{+/+}$ and $SLC7A11^{sut/sut}$ mice***

Mice null for the neuronal cysteine uptake transporter EAAT3 (EAAC1) exhibit gross brain atrophy in association with decreased GSH levels (Aoyama et al 2006). Whether loss of the predominant cyst(e)ine supplier in astrocytes,  $Sx_c^-$ , similarly influences brain morphology was explored. Though quantification of female brain hemisphere area using coronal sections spanning +1.1 to -2.54 bregma revealed a slight decrease in overall brain size in  $SLC7A11^{sut/sut}$  mice as compared  $SLC7A11^{+/+}$  sex-matched littermate controls, this effect was not statistically significant (Fig. 2.1B;  $p = 0.2520$ ; repeated measures two-way ANOVA). Similarly,  $SLC7A11^{sut/sut}$  females showed a slight, but not significant, decrease in cortical area (Fig. 2.1C;  $p = 0.2472$ ), striatal area (Fig. 2.1D;  $p = 0.5675$ ), and corpus callosum area (Fig. 2.1F;  $p = 0.0739$ ), while their lateral ventricle area was indistinguishable from  $SLC7A11^{+/+}$  littermates (Fig. 2.1E;  $p = 0.2941$ ; repeated measures two-way ANOVA). However, a significant reduction in corpus callosum thickness was detected in  $SLC7A11^{sut/sut}$  female as compared to  $SLC7A11^{+/+}$  littermates (Fig. 2.1G;  $p = 0.0399$ ; repeated measures two-way ANOVA). Interestingly, these findings were sex-dependent, as male  $SLC7A11^{sut/sut}$  mouse brains were virtually indistinguishable from their  $SLC7A11^{+/+}$  sex-matched littermate controls with respect to not only corpus callosum thickness, but also hemisphere area, cortical thickness, striatal area, lateral ventricle area, and corpus callosum area (Fig. 2.2).

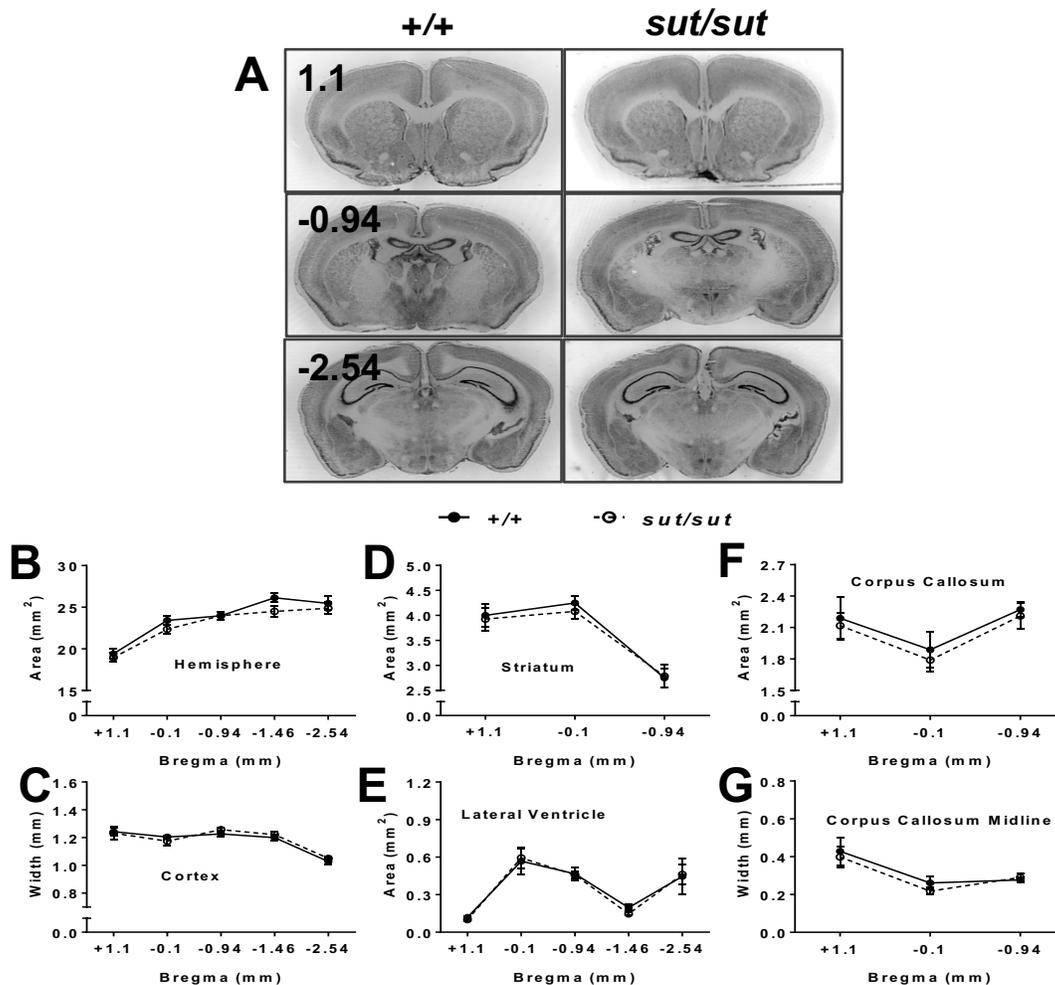

**Figure 2.1 Comparison of gross brain morphology between female *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> mice**

Gross brain morphological measurements were made on thionin-stained coronal brain sections from 12 week old naïve female *SLC7A11*<sup>+/+</sup> (+/+) (n = 4) and *SLC7A11*<sup>sut/sut</sup> (*sut/sut*) (n = 4) littermates. Sections of 40  $\mu$ m thickness were imaged using an Epson Digital Scanner at 720 dpi. Digitized images were processed and quantified using NIH Image J software.

**A)** Representative thionin-stained coronal sections spanning +1.1 to -2.54 anterior to posterior from bregma from +/+ and *sut/sut* mice derived from *sut/+* breeders.

**B-E)** Quantification of (B) hemispheric area, (C) cortical width, (D) striatal area, (E) lateral ventricle area, (F) corpus callosum area, and (G) corpus callosum width from +/+ and *sut/sut* mice was performed over 3-5 coronal sections as described in Materials and Methods. Data are expressed as the mean  $\pm$  SEM width (mm) or area (mm<sup>2</sup>). No significant difference between +/+ and *sut/sut* mice was observed in hemispheric area (B;  $p = 0.2520$ ), cortical thickness (C;  $p = 0.2472$ ), striatal area (D;  $p = 0.5675$ ), lateral ventricle area (E;  $p = 0.2941$ ), or corpus callosum area (F;  $p = 0.0739$ ) as determined by repeated measures two-way ANOVA. \*Corpus callosum width is significantly decreased in *sut/sut* as compared to +/+ littermates (G;  $p = 0.0399$ , repeated measures two-way ANOVA).

**Figure 2.2 Comparison of gross brain morphology between male *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> mice**

Gross brain morphological measurements were made on thionin-stained coronal brain sections from 12 week old naïve male *SLC7A11*<sup>+/+</sup> (+/+) (n = 7) and *SLC7A11*<sup>sut/sut</sup> (*sut/sut*) (n = 8) littermates. Sections of 40  $\mu$ m thickness were imaged using an Epson Digital Scanner at 720 dpi. Digitized images were processed and quantified using NIH Image J software.

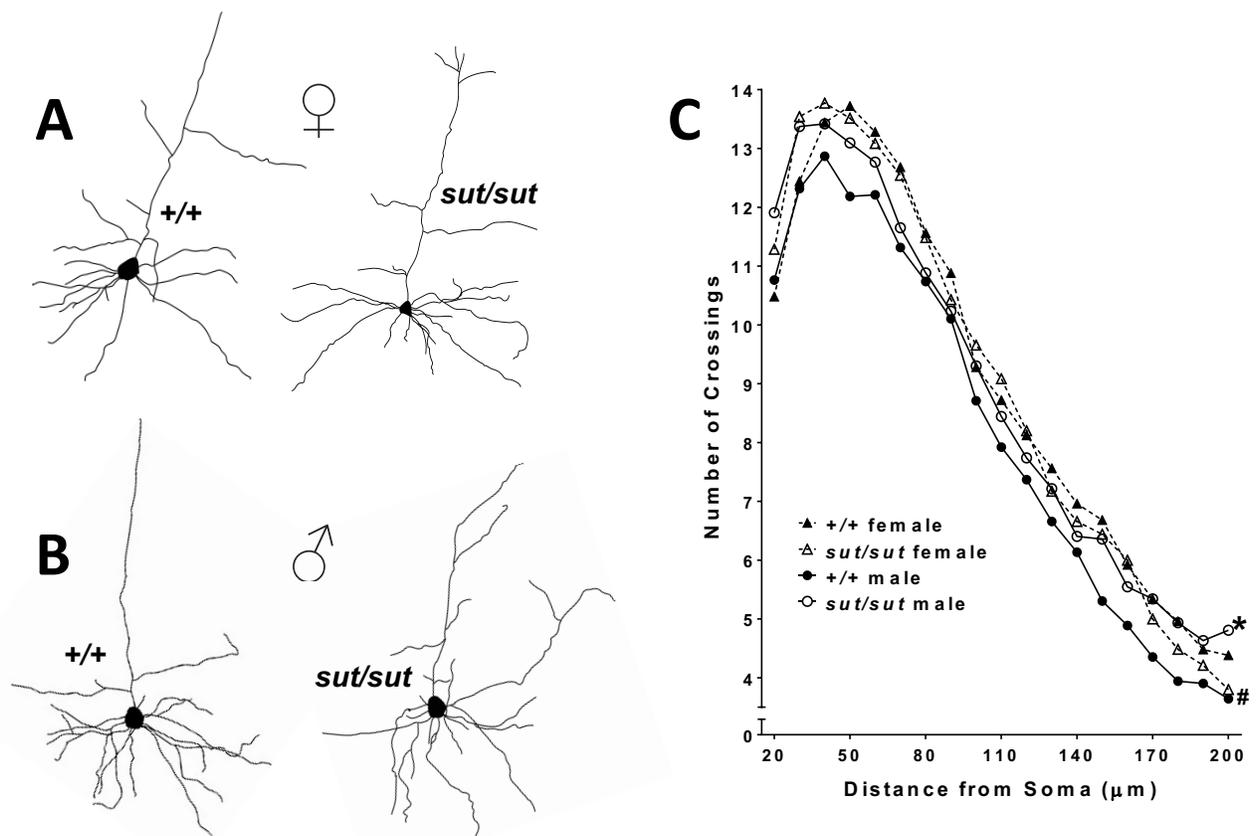

**A)** Representative thionin-stained coronal sections spanning +1.1 to -2.54 anterior to posterior from bregma from +/+ and *sut/sut* mice derived from *sut*/+ breeders.

**B-E)** Quantification of (B) hemispheric area, (C) cortical width, (D) striatal area, (E) lateral ventricle area, (F) corpus callosum area, and (G) corpus callosum width from +/+ and *sut/sut* mice was performed over 3-5 coronal sections as described in Materials and Methods. Data are expressed as the mean  $\pm$  SEM width (mm) or area (mm<sup>2</sup>). No significant difference between +/+ and *sut/sut* mice was observed in hemispheric area (B;  $p = 0.3061$ ), cortical thickness (C;  $p = 0.6010$ ), striatal area (D;  $p = 0.7010$ ), lateral ventricle area (E;  $p = 0.7990$ ), corpus callosum area (F;  $p = 0.6587$ ), or corpus callosum width (G;  $p = 0.6321$ ) as determined using repeated measures two-way ANOVA.

### **Quantification of primary motor cortex layer V pyramidal cells in *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* mice**

The dendritic tree complexity of cortical layer V excitatory pyramidal cells can influence their stereotypical repetitive spike bursting train firing pattern and thus E/I balance (Mainen & Sejnowski 1996). At the cellular level, the dendritic complexity of layer V neurons derived from the primary motor cortex of female *SLC7A11<sup>sut/sut</sup>* mice was indistinguishable from sex-matched *SLC7A11<sup>+/+</sup>* controls (Fig. 2.3C;  $p = 0.8603$ ; two-way ANOVA). Conversely, neurons derived from male *SLC7A11<sup>sut/sut</sup>* mice had enhanced dendritic complexity as compared to *SLC7A11<sup>+/+</sup>* sex-matched littermates (Fig. 2.3C;  $p < 0.0001$ ) and in fact, were indistinguishable from *SLC7A11<sup>sut/sut</sup>* female mice (Fig. 2.3C;  $p = 0.4185$ ). Interestingly, a sex-difference was uncovered in that *SLC7A11<sup>+/+</sup>* males had decreased dendritic complexity as compared to *SLC7A11<sup>+/+</sup>* females (Fig. 2.3C;  $p < 0.0001$ ) (two-way ANOVA). While this data indicates a clear sex difference with respect to dendritic complexity in female and male *SLC7A11<sup>+/+</sup>* mice on the C3H/HeSnJ background, it also indicates that loss of  $Sx_c^-$  in male mice rendered dendritic complexity more “female-like” overall.

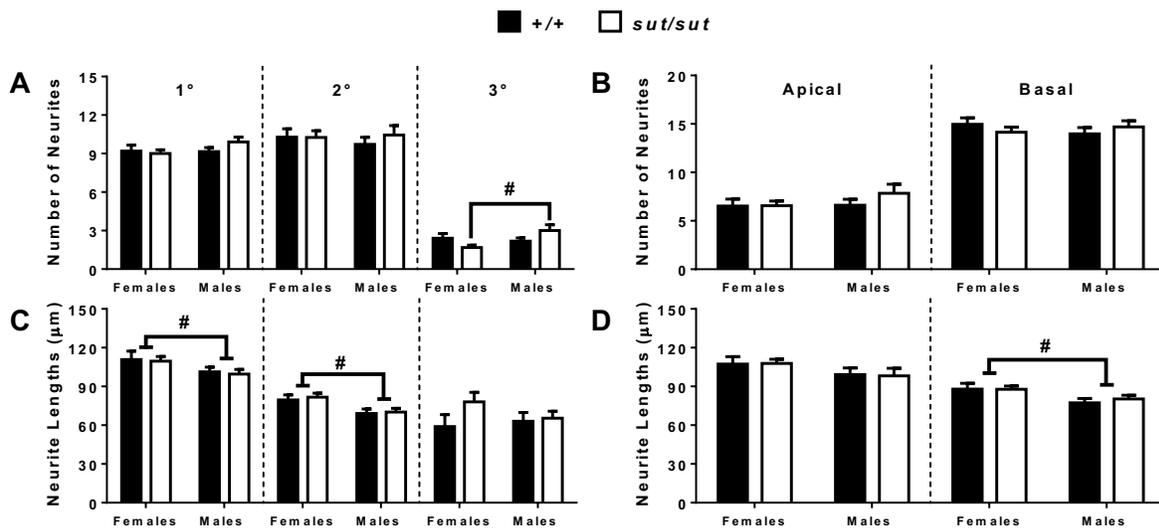

Quantification of primary, secondary, and tertiary neurite numbers and length revealed further sex differences: while no within-sex genotype differences were observed, the number of tertiary neurites in *SLC7A11<sup>sut/sut</sup>* male mice was enhanced as compared to *SLC7A11<sup>sut/sut</sup>* females (Fig. 2.4A;  $p < 0.05$ ; two-way ANOVA with Bonferroni’s multiple comparisons). Moreover, the length of both primary (Fig. 2.4C;  $p = 0.0210$ ) and secondary (Fig. 2.4C;  $p = 0.0014$ ) neurites was enhanced in females versus males (two-way ANOVA), and further classification of primary, secondary, and

**Figure 2.3 Comparison of dendritic complexity between  $SLC7A11^{+/+}$  and  $SLC7A11^{sut/sut}$  mice**

Photomicrographs of Golgi-Cox stained primary motor cortex (PM1) layer V pyramidal cells from naïve  $SLC7A11^{+/+}$  [ $+/+$ ,  $n = 64$  neurons (39M, 25F)] from 7 mice (4M, 3F)] and  $SLC7A11^{sut/sut}$  [ $sut/sut$ ,  $n = 82$  neurons (43M, 39F)] from 9 mice (5M, 4F)] littermates from eight separate litters were reconstructed using Adobe Illustrator as depicted by representative tracings from **(A)** females or **(B)** males.

**C)** The complexity of dendritic arborization in these neurons was explored by Sholl analysis in females and males. Each data point represents the mean number of crossings  $\pm$  SEM. \*Neurons derived from  $sut/sut$  male mice have enhanced dendritic complexity compared to  $+/+$  littermate controls ( $p < 0.0001$ ; two-way ANOVA with Bonferroni's multiple comparisons). #Male  $+/+$  neuronal complexity is also significantly decreased as compared to  $+/+$  females as denoted by the # sign ( $p < 0.0001$ ).

**Figure 2.4 Neurite number and length analysis in female and male *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> mice**

Neurite processes on reconstructed neurons from Figure 2.3 were quantified by NIH Image J analysis.

**A-B)** Bars [black bar (*SLC7A11*<sup>+/+</sup>; +/+) and open bar (*SLC7A11*<sup>sut/sut</sup>; *sut/sut*)] represent the mean ± SEM number of (A) primary, secondary, or tertiary or (B) apical or basal neurites. No significant within-sex genotype differences were observed in the number of neurites at any order (1°, 2°, or 3°) or polarity (apical or basal) quantified (two-way ANOVA). However, *sut/sut* males have an increased number of 3° neurites as compared to female *sut/sut* mice as denoted by the asterisk ( $p < 0.05$ , Two-way ANOVA with Bonferroni's multiple comparisons on log transformed data).

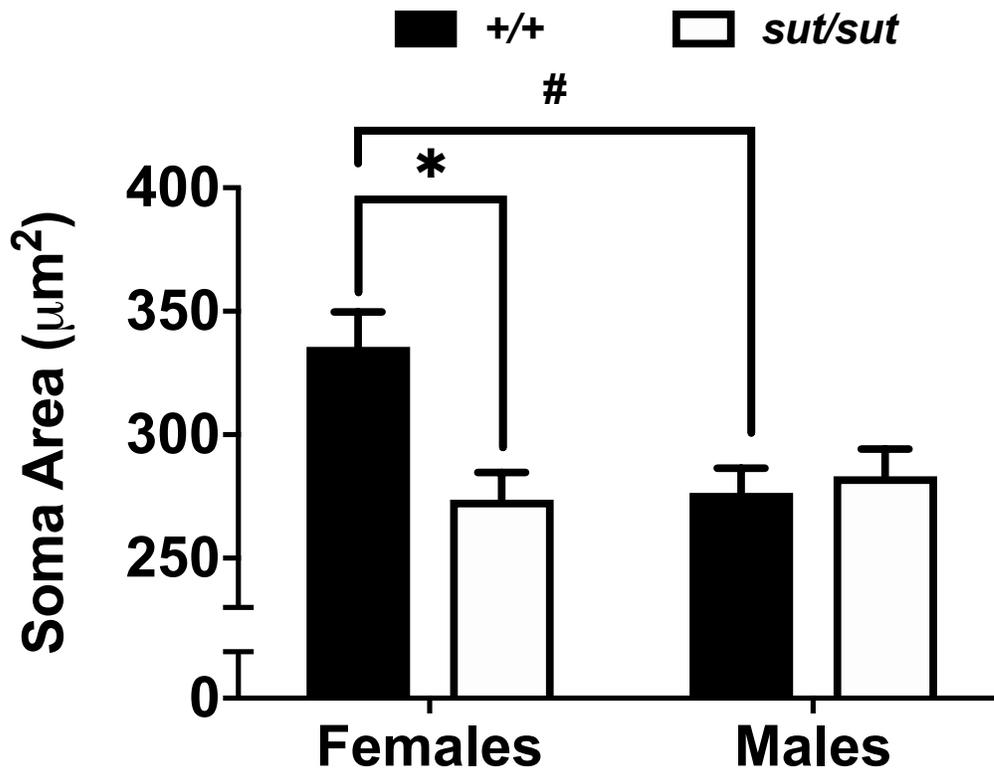

**C-D)** Bars [black bar (+/+) and open bar (*sut/sut*)] represent the mean ± SEM length of (C) primary, secondary, or tertiary or (D) apical or basal neurites. No significant within-sex genotype differences were observed in the length of neurites at any order (1°, 2°, or 3°) or polarity (apical or basal) quantified (two-way ANOVA). #Females have increased 1° ( $p = 0.0210$ ) and 2° ( $p = 0.0014$ ) order as well as basal ( $p = 0.0067$ ) neurite lengths as compared to males (two-way ANOVA with Bonferroni's multiple comparisons).

tertiary neurite polarity into apical or basal revealed enhanced basal neurite length in females as compared to males (Fig. 2.4D;  $p = 0.0067$ ; two-way ANOVA).

Evaluation of the neuronal cell body revealed that the cross-sectional soma area was similar in neurons derived from male *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>mut/mut</sup>* littermates. However, an 18% reduction in cross-sectional soma area was revealed in female *SLC7A11<sup>mut/mut</sup>* as compared to *SLC7A11<sup>+/+</sup>* sex-matched littermate controls (Fig. 2.5;  $335.6 \pm 14.18 \mu\text{m}^2$  for *SLC7A11<sup>+/+</sup>* and  $273.7 \pm 10.98 \mu\text{m}^2$  for *SLC7A11<sup>mut/mut</sup>* mice, mean  $\pm$  SEM;  $p < 0.01$ ; two-way ANOVA with Bonferroni's multiple comparisons). Once more, sex-differences between *SLC7A11<sup>+/+</sup>* male and *SLC7A11<sup>+/+</sup>* female mice were observed (Fig. 2.5;  $p < 0.01$ ; two-way ANOVA with Bonferroni's multiple comparisons), and loss of  $\text{Sx}_c^-$  in female mice rendered their cross-sectional soma area more "male-like" given that they were indistinguishable from *SLC7A11<sup>mut/mut</sup>* male mice (Fig. 2.5; two-way ANOVA with Bonferroni's multiple comparisons).

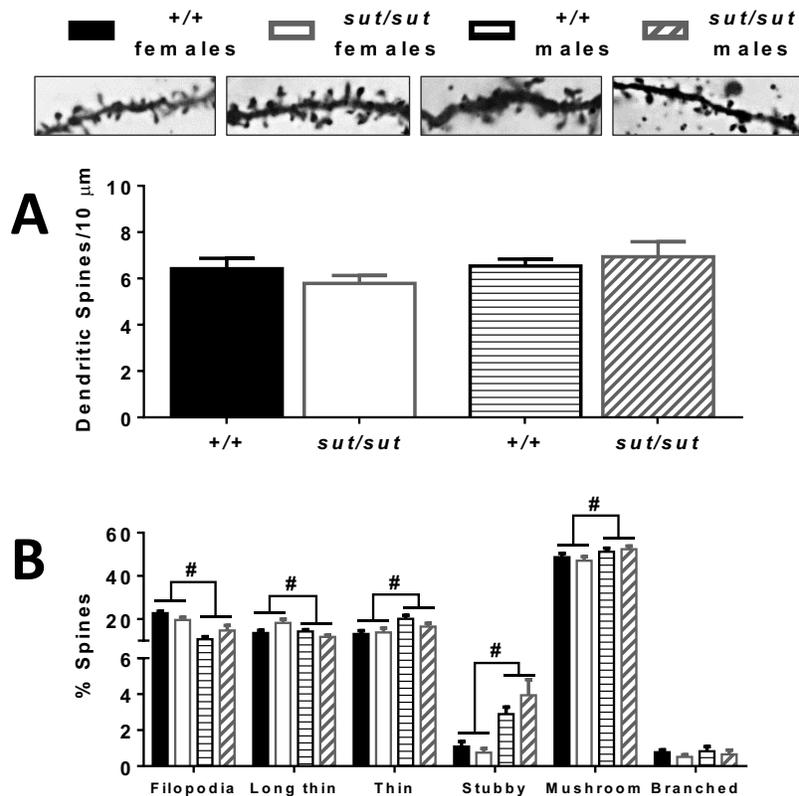

### ***Cortical layer V pyramidal cell dendritic spine analysis***

The majority of fast excitatory synaptic activity occurs at ionotropic glutamate receptors residing on dendritic spines. Moreover, the spine structure-function relationship has been well-characterized, with increases and decreases in spine head width correlating with increases and decreases in glutamate receptors and thus, strengthening and weakening of synaptic efficacy, respectively (Matsuzaki et al 2001, Noguchi et al 2005). Herein, the head width and length of spines were used for categorical classification to determine the proportion of nascent (filopodia, long thin), immature (thin), or mature (stubby, mushroom, branched) dendritic spines

**Figure 2.5 Soma analysis in female and male *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> mice**

The cross sectional soma area of reconstructed neurons from Figure 2.3 were quantified by NIH Image J analysis. Bars [black bar (+/+) and open bar (*sut/sut*)] represent the mean soma area  $\pm$  SEM in females (left) or males (right). \*Neurons derived from female *sut/sut* mice have a decreased soma area compared to +/+ sex-matched littermate controls as denoted by the asterisk ( $p < 0.01$ ); two-way ANOVA with Bonferroni's multiple comparisons). #Female +/+ neurons are also significantly different from male +/+ neurons ( $\#p < 0.01$ ).

**Figure 2.6 Comparison of dendritic spine density and morphology between *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> mice**

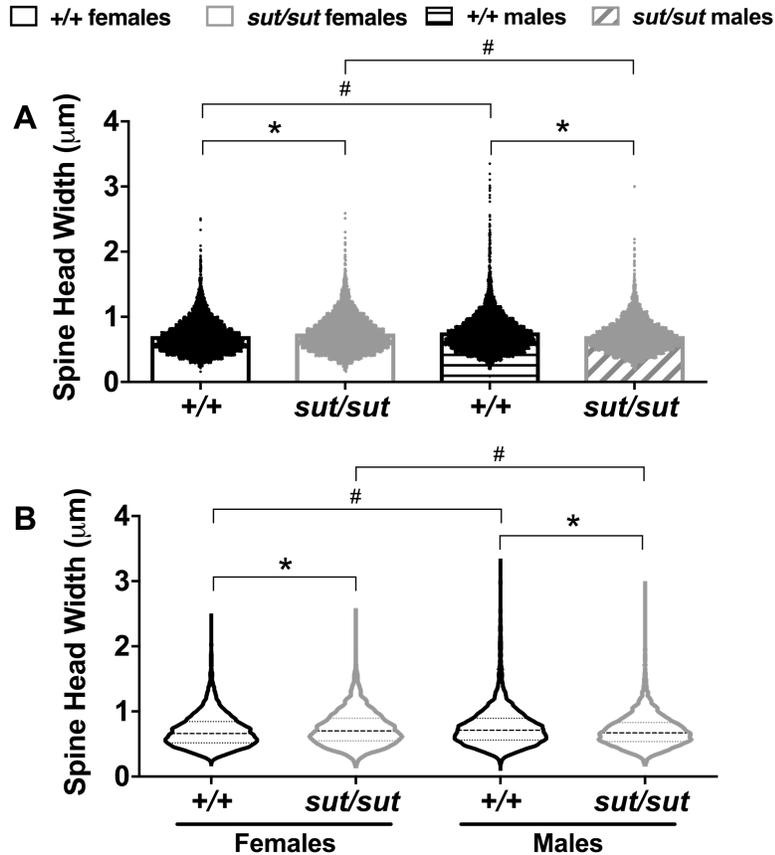

Golgi-Cox stained dendritic spines located on secondary apical dendrites of primary motor cortex layer V pyramidal cells from naïve *SLC7A11*<sup>+/+</sup> [*+/+*, n = 18 neurons (9M, 9F) from 6 mice (3M, 3F)] and *SLC7A11*<sup>sut/sut</sup> [*sut/sut*, n = 17 neurons (8M, 9F) from 6 mice (3M, 3F)] littermates from seven separate litters were analyzed using the *Risher et al.* method as described in materials and methods. The spine density was determined by calculating the number of protrusions/μm of dendrite.

**A)** Bars represent the mean number of spines/10 μm dendritic length ± SEM in *+/+* or *sut/sut* female or male mice. No significant difference between female or male *+/+* and *sut/sut* mice was observed in dendritic spine density in layer V pyramidal cells (two-way ANOVA on log-transformed data). *Inset:* Representative photomicrographs (60x) of secondary apical dendritic spines from Golgi-Cox stained *+/+* and *sut/sut* female or male mice.

**B)** Bars represent the mean percentage of spines ± SEM in female or male *+/+* or *sut/sut* mice categorized as either mushroom, filopodia, stubby, branched, thin, or long thin. No significant within-sex genotype differences in spine typology were observed between *+/+* and *sut/sut* mice (two-way ANOVA on arcsine transformed data). #Males have increased mushroom ( $p = 0.0261$ ), stubby ( $p < 0.0001$ ), and thin ( $p = 0.0060$ ) spines as compared to females whereas females have increased filopodia ( $p < 0.0001$ ) and long thin ( $p = 0.0242$ ) spines as compared to males (two-way ANOVA on arcsine transformed data).

(Risher et al 2014). Assessment of secondary apical dendritic spines on cortical layer V pyramidal cells indicated that spine density was similar in both *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* female and male mice (Fig. 2.6A, two-way ANOVA). Further categorical classification of these spines – facilitated by calculating the spine length to head-width ratios – revealed sex-differences, with male mice exhibiting an increased proportion of mature mushroom ( $p = 0.0261$ ) and stubby ( $p < 0.0001$ ) spines, as well as thin spines ( $p = 0.0060$ ), as compared to female littermates (Fig. 2.6B; two-way ANOVA). Furthermore, female mice demonstrated an increased proportion of nascent filopodia ( $p < 0.0001$ ) and long thin ( $p = 0.0242$ ) spines as compared to males (Fig. 2.6B; two-way ANOVA). These genotype-independent sex-differences demonstrated that a greater proportion of male spines are classified into mature (versus nascent) categories as compared to females, suggesting that male spines may be strengthened overall as compared to females.

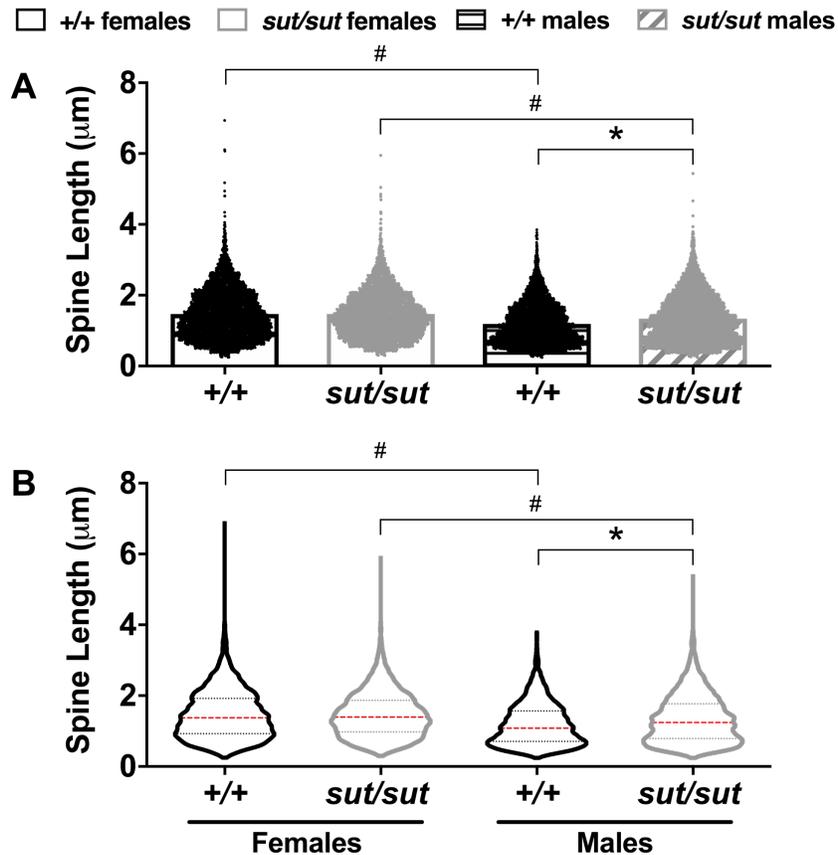

Further analysis of the spine length and head width parameters used to derive the aforementioned classifications revealed that spine head widths were significantly decreased in female *SLC7A11<sup>sut/sut</sup>* mice as compared to *SLC7A11<sup>+/+</sup>* sex-matched littermates (Fig. 2.7A-B;  $p < 0.0001$ ; two-way ANOVA). The opposite occurred in males, wherein *SLC7A11<sup>sut/sut</sup>* male mice had increased spine head widths as compared to sex-matched *SLC7A11<sup>+/+</sup>* controls (Fig. 2.7A-B;  $p < 0.0001$ ; two-way ANOVA). Analysis of sex-differences revealed that spine head widths of *SLC7A11<sup>+/+</sup>* females were enhanced as compared to *SLC7A11<sup>+/+</sup>* males whereas *SLC7A11<sup>sut/sut</sup>* females were decreased as compared to *SLC7A11<sup>sut/sut</sup>* males (Fig. 2.7A-B; two-way ANOVA).

**Figure 2.7 Comparison of spine head width between *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> mice**

The distribution of head width variables from *SLC7A11*<sup>+/+</sup> [+/+; females, n = 4763; males, n = 5056) on 18 neurons (9F, 9M) from 6 mice (3M, 3F)] and *SLC7A11*<sup>sut/sut</sup> [*sut/sut*; females, n = 4430; males, n = 5355) on 17 neurons (9F, 8M) from 6 mice (3F, 3M)] littermates used to derive length-to-width ratios in Figure 2.6 were compared.

**A and B) Top:** Each data point [black circles (+/+) or gray circles (*sut/sut*)] represents the head width of a spine in female (open bars) or male (hatched bars) mice. Bars represent the mean spine head width for each genotype. **Bottom:** the distribution of variables in the above scatterplot were fit to a violin plot. \**Sut/sut* female mice have significantly decreased mushroom spine head widths as compared to +/+ littermate controls ( $p < 0.0001$ ; two-way ANOVA performed on head widths [n = 9 neurons/genotype]); the opposite effect was observed in males ( $p < 0.0001$ ; two-way ANOVA [n = 8-9 neurons /genotype]). Within-genotype sex-differences are indicated by the # signs.

**Figure 2.8 Comparison of spine length between *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> mice**

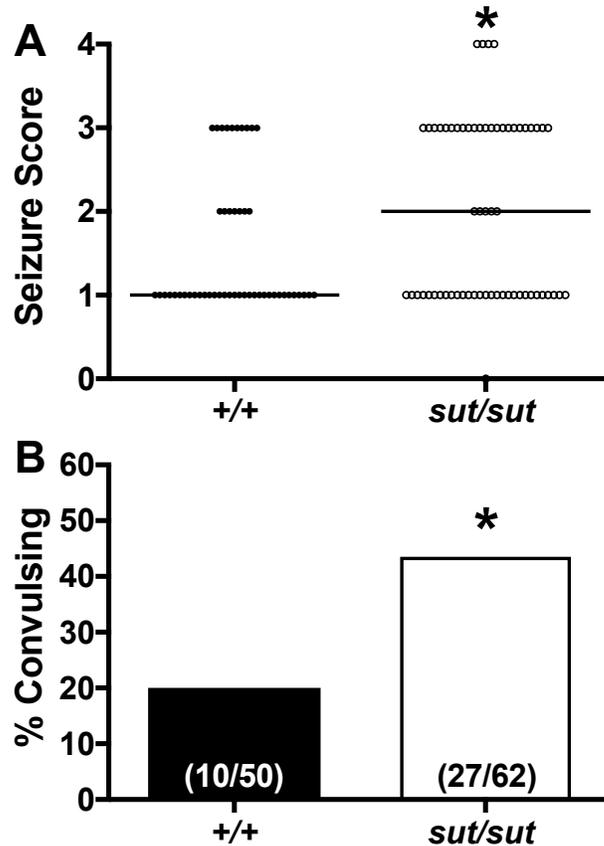

The distribution of spine length variables from *SLC7A11*<sup>+/+</sup> [*+/+*; females, n = 4763; males, n = 5056) on 18 neurons (9F, 9M) from 6 mice (3M, 3F)] and *SLC7A11*<sup>sut/sut</sup> [*sut/sut*; females, n = 4430; males, n = 5355) on 17 neurons (9F, 8M) from 6 mice (3F, 3M)] littermates used to derive length-to-width ratios in Figure 2.6 were compared.

**A and B) Top:** Each data point [black circles (*+/+*) or gray circles (*sut/sut*)] represents the spine length of spine in female (open bars) or male (hatched bars) mice. Bars represent the mean spine length for each genotype. **Bottom:** the distribution of variables in the above scatterplot were fit to a violin plot. \**Sut/sut* male mice have significantly increased mushroom spine length as compared to *+/+* littermate controls (males,  $p < 0.0001$ ; two-way ANOVA performed on head widths [n = 8-9 neurons/genotype/sex]). Within-genotype sex-differences are indicated by the # signs.

with Bonferroni's multiple comparisons). With respect to spine lengths, *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* female mice were identical whereas *SLC7A11<sup>sut/sut</sup>* males had increased spine lengths as compared to *SLC7A11<sup>+/+</sup>* sex-matched littermate controls (Fig. 2.8A-B;  $p < 0.0001$ ; two-way ANOVA with Bonferroni's multiple comparisons). Moreover, analysis of sex-differences indicated that male spine head lengths were decreased as compared to females (Fig. 2.8A-B;  $p < 0.0001$ ; two-way ANOVA). Taken together, these results demonstrate that loss of  $Sx_c^-$  signaling results in a sex-dependent change in layer V cortical pyramidal cell spine head width, with decreases or increases occurring in *SLC7A11<sup>sut/sut</sup>* females or males, respectively, as compared to sex-matched littermate controls.

### ***Functional assessment of E/I balance in *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* mice***

Increases in excitability have been associated with cellular morphological alterations including enhanced dendritic complexity (Klenowski et al 2016, Mainen & Sejnowski 1996), decreased soma size (Hsu et al 2012, Ye et al 2015), and increased spine head width (Zito et al 2009). To determine whether the aforementioned morphological phenotypes affect E/I balance in *SLC7A11<sup>sut/sut</sup>* mice, the seizure threshold of female and male *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* littermates was assessed using the GABA<sub>A</sub>R antagonist PTZ. Within minutes of an acute PTZ dose (42 mg/kg, i.p.), a hypomobility phenotype (seizure score = 1) was evoked in the vast majority of mice regardless of sex or genotype. Despite this initial similarity, the behavioral response of *SLC7A11<sup>sut/sut</sup>* mice progressed such that by the end of the 30 minute

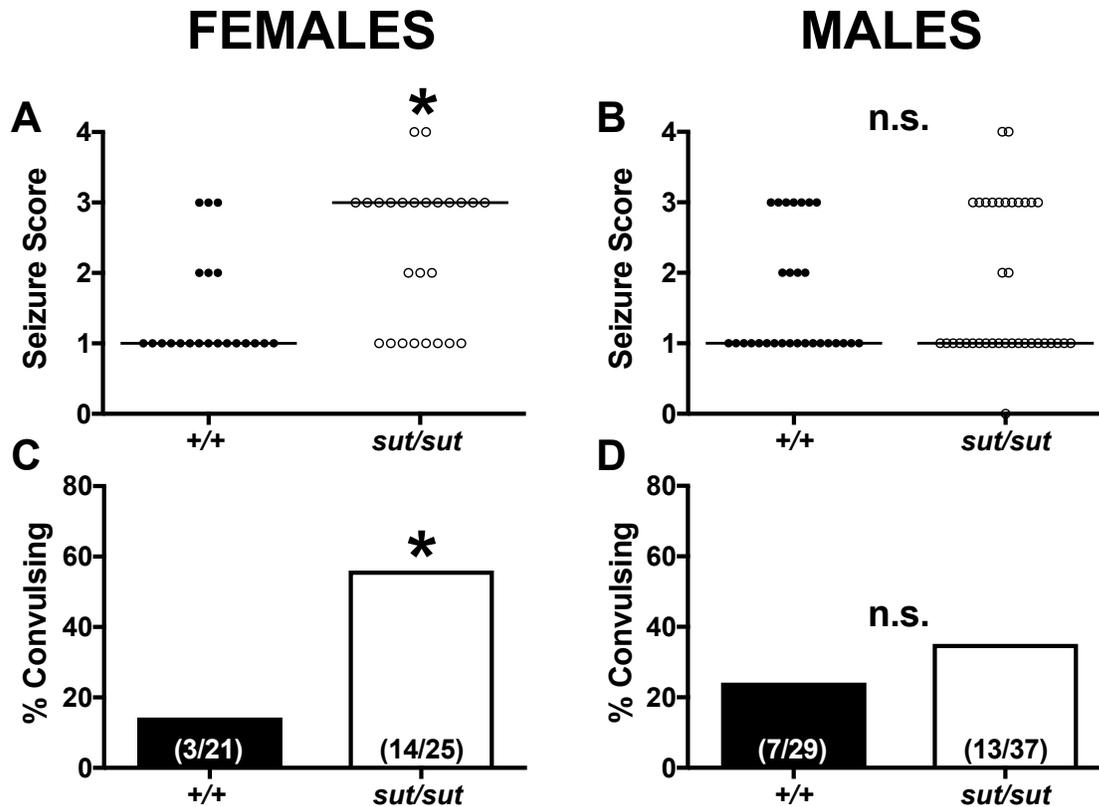

**Figure 2.9** *SLC7A11<sup>sut/sut</sup> mice are hyper-excitable*

Naïve female (n = 21) and male (n = 29) *SLC7A11<sup>+/+</sup>* (+/+, total n = 50) and female (n = 25) and male (n = 37) *SLC7A11<sup>sut/sut</sup>* (*sut/sut*, total n = 62) littermates were treated with a single dose of 42 mg/kg PTZ (i.p.). Seizure behavior was scored using a 5 point scale. Data were pooled from 16 independent experiments performed over 9 months.

**A) Individual seizure scores:** Each data point [closed black circles (+/+) or open circles (*sut/sut*)] represents the maximal seizure score obtained by an individual mouse during a 30 min observation period. Horizontal lines represent the median seizure score for each genotype. \**Sut/sut* mice have a significantly greater seizure score than +/+ littermate controls ( $p = 0.0237$ ; Mann-Whitney U Test).

**B) Convulsive index:** Bars [black bar (+/+) and open bar (*sut/sut*)] represent the proportion (fraction within bars) of mice that experienced a convulsive seizure (seizure score  $\geq 3$ ) in A expressed as a % of total mice exposed to PTZ. \**Sut/sut* mice have a higher convulsive index compared to +/+ littermate controls ( $p = 0.0093$ ; Fisher's Exact Test).

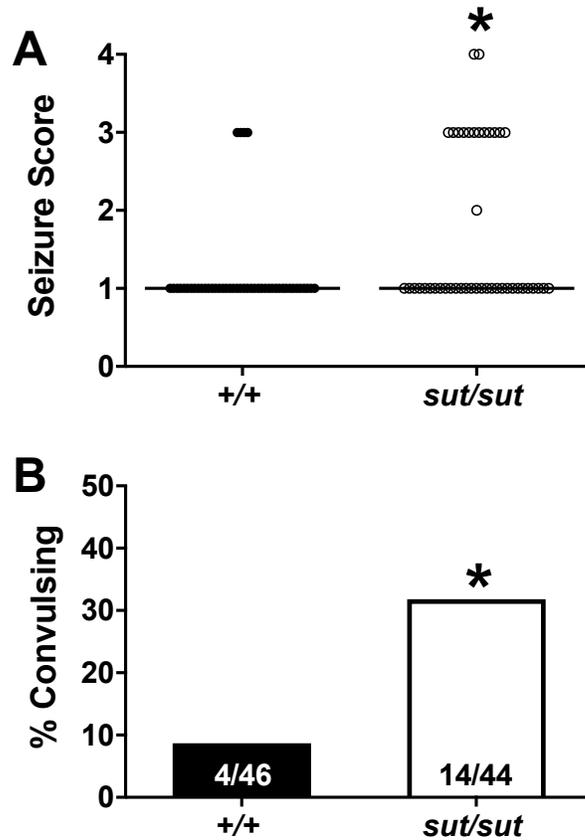

**Figure 2.10 Enhancement of acute PTZ-induced seizure activity in *SLC7A11<sup>sut/sut</sup>* mice differs by sex**

The distribution of variables from mice used to derive Figure 2.9 were grouped and analyzed separately by sex.

**A-B) Individual seizure scores:** Each data point [closed black circles (+/+) or open circles (*sut/sut*)] represents the maximal seizure score obtained by individual female (A) or male (B) mice during a 30 min observation period. Horizontal lines represent the median seizure score for each genotype. *Sut/sut* female ( $p = 0.0030$ ) but not male ( $p = 0.6459$ ) mice have a significantly greater seizure score than +/+ sex-matched littermate controls as denoted by the asterisk (Mann-Whitney U Test).

**C-D) Convulsive index:** Bars [black bar (+/+) and open bar (*sut/sut*)] represent the proportion (fraction within bars) of mice that experienced a convulsive seizure (seizure score  $\geq 3$ ) in A (C) or B (D) as a % of total mice exposed to PTZ. \**Sut/sut* female ( $p = 0.0054$ ) but not male ( $p = 0.4223$ ) mice have a higher convulsive index compared to +/+ sex-matched littermate controls as denoted by the asterisk (Fisher's Exact Test). n.s. denotes not-significant ( $p > 0.05$ ).

**Figure 2.11 Enhancement of acute PTZ-induced seizure activity in male *SLC7A11<sup>sut/sut</sup>* mice uncovered by using a lower dose**

Naïve male *SLC7A11<sup>+/+</sup>* (+/+, total n = 46) and *SLC7A11<sup>sut/sut</sup>* (*sut/sut*, total n = 44) littermates were treated with a single dose of 35 mg/kg PTZ (i.p.). Seizure behavior was scored using a 5 point scale.

**A) Individual seizure scores:** Each data point [closed black circles (+/+) or open circles (*sut/sut*)] represents the maximal seizure score obtained by individual mice during a 30 min observation period. Horizontal lines represent the median seizure score for each genotype. *Sut/sut* male mice have a significantly greater seizure score than +/+ sex-matched littermate controls as denoted by the asterisk ( $p = 0.0031$ , Mann-Whitney U Test).

**B) Convulsive index:** Bars [black bar (+/+) and open bar (*sut/sut*)] represent the proportion (fraction within bars) of mice that experienced a convulsive seizure (seizure score  $\geq 3$ ) in A as a % of total mice exposed to PTZ. \**Sut/sut* male mice have a higher convulsive index compared to +/+ sex-matched littermate controls as denoted by the asterisk ( $p = 0.0081$ , Fisher's Exact Test).

observation period their median seizure score was significantly enhanced compared to *SLC7A11<sup>+/+</sup>* littermates (Fig. 2.9A;  $p = 0.0237$ ; Mann-Whitney U Test). Similarly, *SLC7A11<sup>sut/sut</sup>* mice demonstrated an enhanced convulsive seizure incidence with 43.5% (27/62) achieving a seizure stage  $\geq 3$ , compared to 20% (10/50) of *SLC7A11<sup>+/+</sup>* mice (Fig. 2.9B;  $p = 0.0093$ ; Fisher's Exact Test). The mean latency to convulsive seizure, however, did not differ between genotypes ( $342.8 \pm 59$  and  $387.5 \pm 55$  sec, mean  $\pm$  SEM, for *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* mice, respectively;  $p = 0.6500$ ; unpaired  $t$  test).

Stratification of the variables in Figure 2.9 by sex revealed that female (Fig. 2.10A;  $p = 0.0030$ ), but not male (Fig. 2.10B;  $p = 0.6459$ ), *SLC7A11<sup>sut/sut</sup>* mice significantly contribute to this observed hyperexcitability (Mann-Whitney U Test). While female *SLC7A11<sup>sut/sut</sup>* mice had an elevated convulsive seizure incidence, with 14/25 (56%) of mice achieving a seizure stage  $\geq 3$ , compared to just 3/21 (14.3%) of *SLC7A11<sup>+/+</sup>* mice (Fig. 2.10C;  $p = 0.0054$ ; Fisher's Exact Test), male *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* mice had a similar convulsive seizure incidence (Fig. 2.10D;  $p = 0.4223$ ; Fisher's Exact Test). However, given that a greater proportion of male (7/29; 24.1%) versus female (3/21; 14.3%) *SLC7A11<sup>+/+</sup>* mice had a convulsive seizure, we reasoned that males could have a lower seizure threshold overall that could mask our ability to detect a difference in excitability. To test this, male *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* mice were administered a lower dose of PTZ (35 mg/kg, i.p.) and observed for behavioral seizure activity. Indeed, hyper-excitability in male *SLC7A11<sup>sut/sut</sup>* mice was uncovered at this dose, reflected by their enhanced seizure severity (Fig. 2.11A;  $p = 0.0031$ ; Mann-Whitney U Test) and convulsive seizure incidence (Fig. 2.11B;  $p = 0.0081$ ; Fisher's

Exact Test) as compared to *SLC7A11*<sup>+/+</sup> sex-matched littermate controls. Taken together, the sex-independent decrease in *SLC7A11*<sup>mut/mut</sup> convulsive seizure threshold, unmasked by chemoconvulsant challenge, suggests that *SLC7A11*<sup>mut/mut</sup> mice have a shift in their E/I balance towards excitation as compared to *SLC7A11*<sup>+/+</sup> sex-matched littermate controls.

## 2.5 Discussion

Glutamate transporters, such as the excitatory amino acid transporters (EAATs), have been demonstrated to be important in maintaining E/I balance [reviewed in (Danbolt 2001)]. Despite the well-characterized significance of EAAT signaling, whether and how  $Sx_c^-$ -mediated cystine/glutamate exchange contributes to E/I balance has not, until now, been fully investigated *in vivo*. In this study, we provide the first evidence that sex-dependent morphological differences occur in both female and male  $Sx_c^-$  null mice in comparison to their wild-type littermate controls. These morphological changes occur in association with a sex-independent behavioral hyper-excitability phenotype in *SLC7A11*<sup>mut/mut</sup> mice manifest by a decrease in their acute PTZ convulsive seizure threshold. The latter observation demonstrates that  $Sx_c^-$  signaling contributes to the endogenous network activity that maintains brain E/I balance *in vivo* in both female and male mice.

Two parameters maintained by  $Sx_c^-$  – redox balance and glutamate signaling – could influence brain structure and, in turn, E/I balance. For example, mice null for the neuronal EAAT3 transporter have decreased brain GSH levels that occur in association with age-dependent brain atrophy (Aoyama et al 2006). Moreover, high frequency

stimulation at the hippocampal CA1 synapse results in dendritic spine growth (Engert & Bonhoeffer 1999), which is dependent on glutamate receptor (NMDA) activation (Maletic-Savatic et al 1999). Overall, there was no evidence of gross brain atrophy in most brain regions of female or male *SLC7A11<sup>sut/sut</sup>* mice as compared to *SLC7A11<sup>+/+</sup>* sex-matched littermates. One exception was the thickness of the corpus callosum in *SLC7A11<sup>sut/sut</sup>* females – it was significantly decreased – as compared to *SLC7A11<sup>+/+</sup>* littermates. As the largest inter-hemispheric connection in brain, the corpus callosum is important for integrating information through its primarily excitatory connections (Bloom & Hynd 2005). In fact, transection of the corpus callosum is a therapeutic option to thwart generalization of seizure activity in epileptic individuals (Bogen & Vogel 1962, Van Wagenen & Herren 1940). While callosal thinning could be a result of decreased myelination, and electroencephalographic and behavioral seizures have been reported in animal models of demyelination (Hoffmann et al 2008), it could also result from aberrant development and/or connectivity of callosal projection neurons (Fame et al 2016). With respect to temporal lobe epilepsy, decreased thickness in the posterior and anterior callosal regions have been demonstrated, with anterior corpus callosum thickness positively correlating with epilepsy age of onset (Hermann et al 2003, Weber et al 2007). However, increased corpus callosum thickness at the midline has also been reported in epileptic individuals (Conlon & Trimble 1988). Furthermore, it remains uncertain as to whether changes in callosal thickness are cause or consequence of seizure activity, especially given that diffuse white matter changes are not restricted to the corpus callosum and have been reported to occur throughout the epileptic brain (Arfanakis et al 2002, Gross et al 2006, Scanlon et al 2013).

While gross structural abnormalities of entire brain regions – including the corpus callosum – can perturb E/I balance, so too can morphological changes occurring at the cellular level. For example, the complexity of dendritic arborization increases with neural activity (Redmond et al 2002, Sin et al 2002, Yu & Malenka 2003). Moreover, enhanced dendritic complexity occurs in association with increases in spontaneous excitatory postsynaptic current (EPSC) frequency (Klenowski et al 2016). While we saw no difference in dendritic complexity between female *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* sex-matched littermates, male *SLC7A11<sup>sut/sut</sup>* dendritic complexity was significantly enhanced as compared to *SLC7A11<sup>+/+</sup>* sex-matched controls. Moreover, male *SLC7A11<sup>sut/sut</sup>* dendritic complexity was indistinguishable from that of female *SLC7A11<sup>sut/sut</sup>* mice, whereas *SLC7A11<sup>+/+</sup>* male dendritic complexity was significantly reduced as compared to *SLC7A11<sup>+/+</sup>* females. These sex-differences were further exemplified in examining primary, secondary, and basal neurite lengths, which were enhanced in females versus males. Together, these findings suggest that the enhanced complexity in *SLC7A11<sup>sut/sut</sup>* versus *SLC7A11<sup>+/+</sup>* males may be a result of aberrant, tortuous morphometry versus increases in neurite length. These observed genotype-dependent differences in male mice could plausibly underlie an E/I imbalance manifest by enhanced excitation in *SLC7A11<sup>sut/sut</sup>* as compared to *SLC7A11<sup>+/+</sup>* sex-matched controls.

E/I balance is integrally related to cellular soma size as evidenced by results demonstrating increases in soma area enhance inhibitory input from perisomatic parvalbumin-positive interneurons (Ye et al 2015). Moreover, reductions in soma size occur in association with decreased inhibitory postsynaptic current (IPSC) frequency

(Hsu et al 2012) and increased seizure susceptibility (Hsu et al 2012, McLeod et al 2013). Our results indicate that soma size in female *SLC7A11<sup>sut/sut</sup>* mice is significantly decreased as compared to *SLC7A11<sup>+/+</sup>* sex-matched controls. However, this effect was sex-dependent, as the soma size of male *SLC7A11<sup>sut/sut</sup>* mice was indistinguishable from that of sex-matched *SLC7A11<sup>+/+</sup>* controls. Interestingly, a sex-difference was uncovered in that *SLC7A11<sup>+/+</sup>* males had soma sizes that were significantly smaller than *SLC7A11<sup>+/+</sup>* female mice. Taken together, changes in *SLC7A11<sup>sut/sut</sup>* neuronal morphometry at the cellular level, including enhanced dendritic complexity in males and a reduction in soma area in females, could plausibly facilitate a physiological E/I imbalance, characterized by enhanced excitation, in *SLC7A11<sup>sut/sut</sup>* mice.

The vast majority of fast synaptic neurotransmission occurs at spine heads (Colonnier 1968), and increases or decreases in head width are associated with increases or decreases in glutamate receptor abundance, respectively (Matsuzaki et al 2001). While the overall density of spines/ $\mu\text{m}$  was not altered between female or male mice of either genotype, male mice had an increased proportion of mature spines classified as mushroom or stubby and a concomitant decreased proportion of immature spines, classified as filopodia or long thin, as compared to female mice of either genotype, suggesting that, independent of genotype, male spines may be strengthened as compared to female spines. However, when comparing spine head widths of all dendritic protrusions, we found that head widths of spines measured in male *SLC7A11<sup>+/+</sup>* mice were  $\approx 7\%$  smaller than female *SLC7A11<sup>+/+</sup>* mice. Upon examination of within-sex genotype differences, we found that both spine head widths ( $\approx 4\%$ ) and spine lengths ( $\approx 11\%$ ) were enhanced in male *SLC7A11<sup>sut/sut</sup>* as compared to *SLC7A11<sup>+/+</sup>* sex-

matched mice. The former observation suggests that their spines have increased glutamate receptors (Matsuzaki et al 2001). However, an increase in spine lengths is associated with enhanced filtering of the signal received at the post synaptic density and thus, synaptic weakening (Araya et al 2006), and it is unclear what the overall functional effect of both increased spine head widths and spine lengths would be with regards to synaptic strength. Conversely, female *SLC7A11<sup>sut/sut</sup>* spine head widths were decreased by  $\approx 8\%$  as compared to *SLC7A11<sup>+/+</sup>* littermates, and no changes in spine lengths were observed. While an increase in spine head widths in *SLC7A11<sup>sut/sut</sup>* male mice as compared to *SLC7A11<sup>+/+</sup>* sex-matched littermates is consistent with their hyperexcitable phenotype, a decrease in spine head widths in *SLC7A11<sup>sut/sut</sup>* females is somewhat surprising, given that they too have a decreased convulsive seizure threshold. However, it is possible that a reduction in synaptic strength at excitatory pyramidal cell synapses in female *SLC7A11<sup>sut/sut</sup>* mice could be a compensatory response to a hyper-excitable circuit elicited by other changes – such as a reduction in soma size and inhibitory drive (Hsu et al 2012, McLeod et al 2013, Ye et al 2015).

Any of the aforementioned morphometric alterations could result in an E/I imbalance. Indeed, both female and male *SLC7A11<sup>sut/sut</sup>* mice exhibited increased seizure severity and convulsive seizure incidence as compared to *SLC7A11<sup>+/+</sup>* sex-matched littermate controls in response to a single dose of the chemoconvulsant PTZ. Thus, despite sex-dependent brain morphological differences, *SLC7A11<sup>sut/sut</sup>* mice exhibit a sex-independent functional hyper-excitability. These findings raise the intriguing possibility that morphological sex-differences serve to maintain E/I balance in brains of female and male wild-type mice, and these sex-differences are, at least in part,

maintained by  $Sx_c^-$  signaling. For instance, the decreased dendritic complexity in male versus female  $SLC7A11^{+/+}$  mice may be integral in dampening aberrant connectivity in males. In male mice, loss of  $Sx_c^-$  renders complexity more “female like”, and this occurs in association with hyper-excitability. With respect to soma size, the increased soma area in female versus male  $SLC7A11^{+/+}$  mice may be integral for females in maintaining an elevated level of somatic inhibitory input to thwart aberrant neural activity. In female mice, loss of  $Sx_c^-$  renders their soma area more “male like”, and this too occurs in association with hyper-excitability. That a null mutation in  $Sx_c^-$  eliminates morphological sex differences – and decreases convulsive seizure threshold – is suggestive that morphological sex differences exist to prevent adverse behavioral outcomes, such as an E/I imbalance.

Taken together, our results are the first to detail a role for  $Sx_c^-$  in maintenance of cellular morphology. Specifically, we found that female  $SLC7A11^{sut/sut}$  mice with a null mutation in the substrate specific light chain of  $Sx_c^-$  demonstrate decreased corpus callosum thickness, cross-sectional soma area, and dendritic spine head widths as compared to  $SLC7A11^{+/+}$  sex-matched littermate controls. Conversely, male  $SLC7A11^{sut/sut}$  mice exhibited enhanced dendritic complexity and spine head widths compared to  $SLC7A11^{+/+}$  mice. These sex-dependent morphological alterations occur in association with an E/I imbalance manifest by a decreased convulsive seizure threshold when provoked with the  $GABA_A$ R antagonist PTZ. More broadly, these findings raise the intriguing possibility that morphological sex-differences serve to maintain E/I balance in brain, and these sex-differences are, at least in part, maintained by  $Sx_c^-$  signaling.

### **Chapter 3: Decreased epileptogenesis in mice lacking the system $x_c^-$ transporter occurs in association with a reduction in AMPA receptor subunit GluA1**

**This chapter is near duplicate of the submitted manuscript:**

Sears, Sheila M.S., Hewett, James A., and Hewett, Sandra J. (2018) Decreased epileptogenesis in mice lacking the System  $x_c^-$  transporter occurs in association with a reduction in AMPA receptor subunit GluA1. *Submitted*.

### 3.1 Summary

Although the cystine/glutamate antiporter System  $x_c^-$  ( $Sx_c^-$ ) plays a permissive role in glioma-associated seizures, its contribution to other acquired epilepsies has not been determined. As such, the present study investigates whether and how  $Sx_c^-$  contributes to the PTZ chemical kindling model of epileptogenesis. Male *SLC7A11<sup>lut/lut</sup>* mice and their wild-type *SLC7A11<sup>+/+</sup>* littermates were administered PTZ (i.p.) daily for up to 21 days (kindling paradigm). Seizure severity was scored on a five-point behavioral scale. Mossy fiber sprouting, cellular degeneration, and  $Sx_c^-$  light chain (xCT) messenger RNA (mRNA) was explored using Timm staining, thionin staining, or real-time quantitative polymerase chain reaction (qPCR), respectively. Levels of reduced and oxidized glutathione and cysteine were determined via high performance liquid chromatography (HPLC). Plasma membrane protein levels of glutamate and GABA receptor subunits as well as the  $K^+/Cl^-$  co-transporter KCC2 were quantified in brains of *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>lut/lut</sup>* mice via Western blot analysis. Our results demonstrate that repeated administration of PTZ produced chemical kindling in only 50% of *SLC7A11<sup>lut/lut</sup>* mice as compared to 82% of *SLC7A11<sup>+/+</sup>* littermate control mice. Kindling did not result in any changes in xCT mRNA levels assessed in *SLC7A11<sup>+/+</sup>* mice. No cellular degeneration or mossy fiber sprouting was discernible in either genotype. Except for a small, but significant, decrease in oxidized cysteine in the hippocampus, no other change in measured redox couples were determined in *SLC7A11<sup>lut/lut</sup>* mice. Cortical levels of the AMPA receptor subunit GluA1 were decreased in *SLC7A11<sup>lut/lut</sup>* mice as compared to *SLC7A11<sup>+/+</sup>* littermates, whereas all other proteins tested showed no difference between genotypes. This study provides the first evidence that  $Sx_c^-$  signaling contributes to epileptogenesis in the PTZ kindling model of acquired epilepsy.

Further data indicate a reduction in AMPA receptor signaling could underlie the resistance to PTZ kindling uncovered in *SLC7A11<sup>sut/sut</sup>* mice.

### 3.2 Introduction

System  $x_c^-$  ( $Sx_c^-$ ) is a sodium-independent anionic amino acid antiporter comprised of two protein components linked via a disulfide bridge: xCT (encoded by *SLC7A11*), the light chain that confers substrate specificity, and 4f2hc (encoded by *SLC3A2*), the associated glycoprotein heavy chain that traffics xCT to the plasma membrane (Bassi et al 2001, Sato et al 1999). While xCT expression is inducible in a number of tissues, its constitutive expression is limited to the central nervous system (CNS) and lymphoid organs, including the thymus and spleen (Sato et al 2002, Taguchi et al 2007). Within the CNS, xCT is detected in most major brain regions with studies investigating its cellular source demonstrating it is predominantly of astrocytic origin (Ottestad-Hansen et al 2018, Pow 2001).

$Sx_c^-$  imports cystine (CySS) and exports glutamate (Glu) with 1:1 stoichiometry across the cellular plasma membrane (Bannai 1986). Early functional characterization of  $Sx_c^-$  established its fundamental physiological role as a cellular CySS supplier. Following  $Sx_c^-$ -mediated uptake, CySS is rapidly reduced to cysteine (Cys), a critical component of many structural, catalytic, and regulatory domains of proteins and a precursor for the essential thiol antioxidant, glutathione (GSH) (Sato et al 1998). Cys is also directly exported from the cell via neutral amino acid transporters (Banjac et al 2008). Thus,  $Sx_c^-$  regulates intracellular and extracellular thiol redox systems (Banjac et al 2008, Sato et al 1998). Additionally, several studies have determined that  $Sx_c^-$  contributes significantly to the ambient extracellular glutamate pool that bathes the CNS *in vivo* (De Bundel et al 2011, Massie et al 2011b, McCullagh & Featherstone 2014).

Alterations in redox homeostasis adversely affect neuronal synaptic plasticity (Almaguer-Melian et al 2000, Robillard et al 2011), stressing the importance of redox balance in the normal function of brain network activity. Additionally, glutamate released from astrocytes is known to modulate neuronal excitability and enhance synaptic strength [for review see (De Pitta et al 2016)]. Further, multiple studies demonstrate that changes in redox balance and/or extracellular glutamate levels could be permissive in generating ictal activity. For example, mice under chronic oxidative stress show increased incidence of spontaneous and handling-induced seizures, which occurs in association with decreased expression of the glial glutamate transporters (GLT-1 and GLAST) (Liang & Patel 2004). Diminished glutamate uptake in mice null for the glutamate transporters GLT-1 or GLAST occurs in association with spontaneous seizures or prolonged seizure duration in an amygdaloid kindling model, respectively (Tanaka et al 1997, Watanabe et al 1999). Moreover, increased  $Sx_c^-$ -mediated cystine/glutamate exchange in glioma (Ye et al 1999) occurs in association with elevated glutamate levels (Ye & Sontheimer 1999), and pharmacological inhibition of  $Sx_c^-$  reduces peritumoral glutamate levels in human glioblastoma patients (Robert et al 2015) as well as seizure frequency in glioma-bearing mice (Buckingham et al 2011). Whether  $Sx_c^-$  is involved in non-tumor associated seizure generation is not known, although xCT levels are upregulated in resected hippocampi from temporal lobe epileptics (Lewerenz et al 2014). Finally, male transgenic xCT null mice require an elevated dose of pilocarpine or KA to elicit behavioral seizures – in addition to demonstrating decreased seizure severity and mortality in response to an acute dose of

NMDA – suggesting that  $Sx_c^-$  signaling is permissive in generating acute seizure activity (De Bundel et al 2011).

The dual regulation of redox systems and glutamate homeostasis by  $Sx_c^-$  and the potential for alterations in such to regulate brain ictal activity prompted our interest in the possibility that this antiporter may also contribute to the aberrant changes that predispose the CNS to develop epilepsy. Thus, the overall goal of this study was to explore the contribution of  $Sx_c^-$  to epileptogenesis by comparing PTZ kindling in mice wild-type or null for the *SLC7A11* gene.

### **3.3 Materials and Methods**

#### **3.3.1 Animals**

Mice were maintained in the AALAC accredited Laboratory Animal Resource facility of Syracuse University on a 12 hr light/dark schedule (7am/7pm). Standard mouse chow and water were provided *ad libitum*. Experiments were carried out using male mice (8-12 weeks at start of experimentation) in accordance with the National Institutes of Health guidelines for the use of experimental animals as approved by the Institutional Animal Care and Use Committee of Syracuse University. Purchased C57BL/6J mice [Jackson Laboratories (JAX) Stock #000664] were allowed to acclimatize to the facility for at least one week prior to any manipulations. Wild-type (*SLC7A11<sup>+/+</sup>*) and xCT mutant (*SLC7A11<sup>sut/sut</sup>*) mice were bred in-house from heterozygous (*SLC7A11<sup>+ / sut</sup>*) breeding units (F1) that were obtained by crossing *SLC7A11<sup>sut/sut</sup>* male mice (JAX, Stock #001310) with *SLC7A11<sup>+/+</sup>* female C3H/HeSnJ mice (JAX, Stock #000661). F2 *SLC7A11<sup>+ / sut</sup>* progeny were also used as breeding units

for studies. Genotyping was performed via PCR analysis of tail genomic DNA samples: +/+ primers, 5'- GAA GTG CTC CGT GAA GAA GG -3' (forward), 5'- ATC TCA ATC CTG GGC AGA TG -3' (reverse); *sut/sut* primers, 5'- CCA CTG TTG TAG GTC AGC TTA GG -3' (forward), 5'- CAG GAC CTG TGA ATA TGA TAG GG -3' (reverse). Mice were segregated by sex at weaning and placed two to three per cage such that at least one mouse of each genotype was represented. These breeding and housing strategies were employed to control for environmental differences, genetic background influences, and genetic drift. Gross morphological analysis of *SLC7A11<sup>sut/sut</sup>* and *SLC7A11<sup>+/+</sup>* male mouse brains at 12 weeks of age revealed no significant differences (not shown).

### **3.3.2 PTZ Kindling**

Five days prior to each study, mice were acclimated to handling by performing mock daily intraperitoneal (i.p.) injections, which consisted of inverting the mouse and rubbing its abdomen. They were also acclimatized to the procedure room for at least one hour on each day of injection. PTZ (Sigma Chemical Co., St. Louis, MO), made fresh daily, was dissolved in saline and filter sterilized. PTZ was administered i.p. in a volume of 10 ml/kg body weight. C3H/HeSnJ or C57BL/6J mice were dosed at 35 mg/kg or 39 mg/kg, respectively, once daily for up to 21 days. The dose for C3H/HeSnJ and C57BL/6J mice was chosen following initial dose ranging studies to determine the PTZ seizure threshold [Supplementary Fig. S1 and (Claycomb et al 2011), respectively]. Following each injection, mice were monitored for 30 min and the time and severity of behavioral seizures scored and recorded by an observer blinded to genotype using a five-point modified Racine scale (0 - 4: 0 = no behavioral change; 1 = hypoactivity; 2 =

myoclonus; 3 = generalized convulsion with righting reflex; 4 = generalized convulsion with loss of righting reflex) [For full description see Table 1 (Racine 1972)]. Mice were deemed kindled after exhibiting convulsive seizures ( $\geq$  stage 3) on three consecutive days, after which PTZ injections were stopped. Ten days later, the permanence of the kindled state was assessed by rechallenging with PTZ. The percentage of permanently kindled mice was determined by dividing the number of animals with a maximum seizure score  $\geq$  3 by the total number of animals injected. It should be noted that six *SLC7A11<sup>sut/sut</sup>* mice were *a priori* excluded from the study as they responded to the first injection with a convulsive seizure (behavioral score  $\geq$  3) making any further reduction in seizure threshold elicited by the kindling protocol (*vide supra*) indeterminable.

### **3.3.3 Real-Time Quantitative Polymerase Chain Reaction (q-PCR)**

Total RNA, isolated using TRIzol reagent (Invitrogen, Carlsbad, CA) from cortical or hippocampal tissue of PTZ-kindled, PTZ-non-kindled, or saline-injected C57BL/6J mice one day following the final injection with PTZ or saline, was subjected to first-strand cDNA synthesis. cDNA was subjected to real-time quantitative polymerase chain reaction (qPCR) in a reaction containing mouse-specific primers for the system  $x_c^-$  light chain (xCT) (*SLC7A11*, Mm01292531\_m1, Taqman Gene Expression Assays, Applied Biosystems, Foster City, CA) and the reference gene hypoxanthine guanine phosphoribosyl transferase (*HPRT*, Mm01545399\_m1, Taqman Gene Expression Assays, Applied Biosystems, Foster City, CA) along with TaqMan Universal PCR MasterMix (Applied Biosystems, Foster City, CA). HPRT expression levels were stable under our experimental conditions. A serial dilution of cortical or hippocampal cDNA

demonstrated that the calculated slope of the line comparing  $\Delta C_T$  ( $C_T$  value of xCT –  $C_T$  value of HPRT) versus input cDNA was -0.007606 or -0.000905, respectively, and that the efficiency of both primers was >90% in either tissue. Reactions were performed in duplicate or triplicate using an Eppendorf Realplex<sup>2</sup> under the following conditions: 50°C for 2 min and 95°C for 10 min followed by 40 amplification cycles (95°C for 15 sec and 60°C for 1 min). Data analysis was performed using the comparative cycle threshold method ( $\Delta\Delta C_T$ ), where  $C_T$  values of xCT were normalized to HPRT  $C_T$  values from the same sample and compared to the calibrator  $C_T$  values (saline controls) to determine the relative fold increase in xCT mRNA.

### **3.3.4 Timm and Thionin Staining**

Mossy fiber sprouting, elucidated by Timm staining, was quantified in the supragranular layer of the dentate gyrus (DG) by an observer blinded to the experimental condition. Brain slices from PTZ kindled *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* mice and saline-injected *SLC7A11<sup>+/+</sup>* mice were sacrificed 16-17 days after kindling acquisition or cessation of saline injections by transcardial perfusion with a proprietary (FD Rapid TimmStain Kit; FD Neuro Technologies, Inc., Baltimore, MD) sodium sulfide-containing perfusate (Perfusate A plus B), followed by 4% paraformaldehyde (PFA) in 0.1 M phosphate buffer (PB). Following removal from the cranium, brains were post-fixed in 4% PFA for 24 hr (4°C), transferred to a 30% sucrose solution in 0.1 M PB for 72 hr (4°C), and then snap-frozen on dry ice in Optimal Cutting Temperature (O.C.T.) compound (Tissue-Tek, Torrance, CA) prior to storage at -80°C. Frozen brains were cut serially ( $\approx$ -0.94 – -2.46 mm posterior to bregma) into 40  $\mu$ m coronal sections, mounted

on gelatin-coated slides (FD Neuro Technologies, Inc., Baltimore, MD), air dried at room temperature for 24 hours, then stored in a light-protected box at -20°C. Timm staining was carried out per manufacturer's instructions (FD Rapid TimmStain Kit) with the exception that the time in the silver nitrate developing solution (Solution A, B, C, and D) was extended to 55-70 min. Mossy fiber sprouting was quantified using a six-point rating scale (0-5) developed by Cavazos et al.(Cavazos et al 1991): 0 = no Timm granules; 1 = patchy distribution of sparse granules in supragranular layer; 2 = continuous distribution of granules in supragranular layer; 3 = continuous distribution of granules with patches of confluency in supragranular layer; 4 = prominent granules that form a dense, confluent laminar band in supragranular layer; 5 = prominent granules that form a dense, confluent laminar band in the supragranular layer that extend into the inner molecular layer. A Timm score for each mouse was determined by calculating the median of the scores assigned to the left and right DG at  $\approx$ -1.94 mm posterior to bregma. Tissue sections within 80  $\mu$ m of those processed for Timm staining were thionin-stained (Sigma Chemical Co., St. Louis, MO) as we previously describe to assess for any neurodegeneration. All tissue analyses were performed on identically processed photomicrographs acquired using a DP73 digital color camera (Olympus, Tokyo, Japan) mounted on an Olympus IX50 inverted microscope (Olympus, Tokyo, Japan).

### **3.3.5 Reduced/Oxidized Glutathione and Cysteine Measurements**

Fully anesthetized naïve *SLC7A11<sup>+/+</sup>* or *SLC7A11<sup>sut/sut</sup>* mice were perfused transcardially with ice-cold phosphate buffered saline (PBS, 1x). Hippocampal and

cortical tissue were rapidly dissected and snap-frozen separately in liquid nitrogen. The concentrations of reduced and oxidized glutathione (GSH and GSSG) and cysteine (Cys and CySS) were determined via high performance liquid chromatography (HPLC) by the Emory-Children's Pediatric Biomarkers Core facility.

### **3.3.6 Immunoblotting**

#### *3.3.6.1 Plasma membrane protein isolation:*

Naïve *SLC7A11<sup>+/+</sup>* or *SLC7A11<sup>mut/mut</sup>* mice were perfused transcardially with ice-cold 1x PBS under full anesthesia. Bilateral hippocampi and cortices were dissected, snap frozen in liquid nitrogen separately, and stored at -80°C prior to use. Plasma membrane proteins were isolated from pooled hippocampi (2-5 mice/sample) or bilateral cortices (one mouse/sample) using an aqueous two-phase separation method as per manufacturer's instructions (Plasma Membrane Protein Extraction Kit, Abcam, Cambridge, U.K.). Isolated proteins were suspended in 0.5% Triton X-100 in PBS. Samples were stored at -80°C until immunoblotting. Protein concentrations were quantified using the BCA assay kit (Pierce, Rockford, IL).

#### *3.3.6.2 Gel electrophoresis and protein detection*

Protein samples (7.5 µg) were separated by 8% SDS-PAGE under reducing (10mM dithiothreitol) and chaotropic (8M urea) conditions followed by electrophoretic transfer to a PVDF membrane (Bio-Rad; Hercules, CA). Membranes were blocked for one hr at room temperature (Odyssey® blocking buffer, LI-COR Biosciences; Lincoln, NE) then probed overnight (4°C) with the following antibodies: anti-Na<sup>+</sup>/K<sup>+</sup> ATPase α1

mouse monoclonal antibody (1:750; Abcam; RRID: AB\_306023); anti-GluA1 rabbit polyclonal antibody (1:750; Abcam; RRID:AB\_2113447); anti-GluA2 rabbit polyclonal antibody (1:750; Abcam; RRID:AB\_2232655); anti-GluN1 rabbit monoclonal antibody (1:750; Cell Signaling; RRID: AB\_1904067); anti-GluN2A rabbit polyclonal antibody (1:750; Cell Signaling; RRID: AB\_2112295); anti-GluN2B rabbit polyclonal antibody (1:750; Cell Signaling; RRID: AB\_1264223); anti-GABA<sub>A</sub>R $\alpha$ 1 rabbit polyclonal antibody (1:3000; Abcam; RRID: AB\_732498); anti-K<sup>+</sup>/Cl<sup>-</sup> co-transporter (KCC2) rabbit polyclonal antibody (1:750; Abcam; RRID: AB\_881571). Species-specific secondary antibodies labeled with spectrally distinct IRDye® fluorescent dyes (LI-COR Biosciences, Lincoln, NE) were used to detect primary antibodies (1 hr at 25°C) (1:10,000 dilution). Results were recorded on a LI-COR ODYSSEY® Fc Imaging system (LI-COR Biosciences; Lincoln, NE) and protein levels quantified using Image Studio 3.1 (LI-COR Biosciences; Lincoln, NE). Each protein was normalized to the Na<sup>+</sup>/K<sup>+</sup> ATPase levels contained in each lane. The signal intensity pertaining to the amount of hippocampal or cortical protein per lane (7.5  $\mu$ g) was determined to be in the linear range for each antibody at their respective dilution (data not shown).

### **3.3.7 Statistical Analysis**

All statistical analyses were performed using GraphPad Prism (Version 6.0.1, Graphpad Software, Inc., La Jolla, CA). Curves depicting kindling acquisition as a function of time were compared using a log-rank test. Two-way ANOVA or unpaired *t* test was used to compare seizure latencies, mouse weight, and the concentrations of reductants/oxidants. Proportions indicating the percent of mice convulsing were

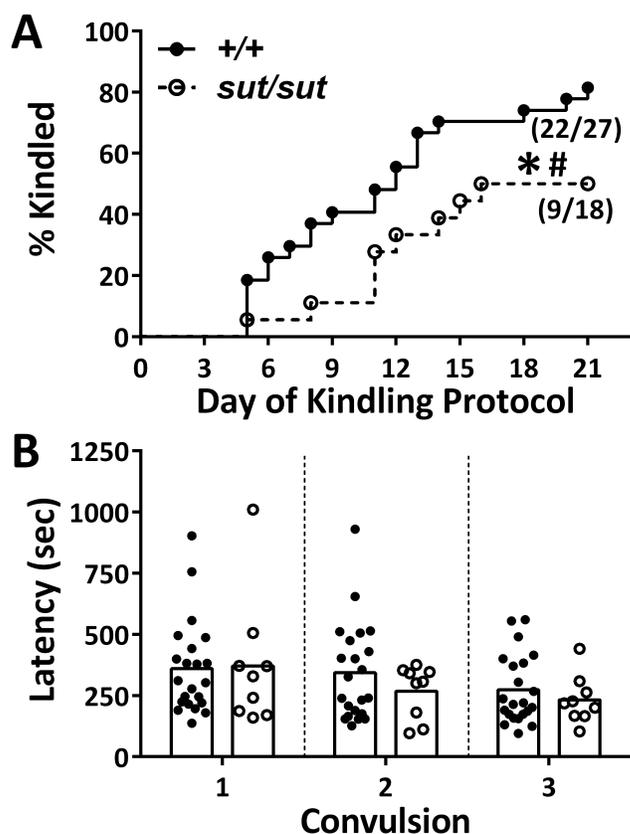

compared using a Fisher's exact test. The Mann-Whitney U test was used to compare Timm scores. Prior to parametric analysis, qPCR data were transformed to the geometric means whereas immunoblot data was log transformed ( $y = \log(y+1)$ ) and compared using one-way ANOVA or an unpaired  $t$  test, respectively. In all cases, significance was set at  $p < 0.05$ .

### 3.4 Results

#### ***Kindling acquisition, maintenance and mortality***

Irrespective of the mouse's genotype, the rate of kindling steadily increased over the 21-day dosing paradigm (Fig. 3.1A) with the mean latency to kindle being  $10.3 \pm 1.1$  and  $11.4 \pm 1.2$  days for *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>mut/mut</sup>* mice, respectively ( $p = 0.54$ , unpaired  $t$  test). Although the latency to convulsive seizure on each of the three consecutive days leading up to and inclusive of the kindled state was similar between *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>mut/mut</sup>* littermates (Fig. 3.1B;  $p = 0.40$ , two-way ANOVA), kindling acquisition was significantly reduced in *SLC7A11<sup>mut/mut</sup>* (9/18; 50%) as compared to *SLC7A11<sup>+/+</sup>* (22/27; 81.5%) (Fig. 3.1A;  $p = 0.02$ , log-rank test).

Permanency of the kindled state, determined by rechallenge with PTZ ten days after the third convulsion, was neither 100% for either genotype nor statistically significant between genotypes with only 82% of the *SLC7A11<sup>+/+</sup>* (18/22) and 78% of *SLC7A11<sup>mut/mut</sup>* (7/9) responding to the PTZ challenge with a seizure score of  $\geq 3$  ( $p = 1.00$ , Fisher's exact test). The latency to convulsion upon rechallenge also did not differ

**Figure 3.1 Comparison of PTZ kindling acquisition and convulsive seizure latency between  $SLC7A11^{+/+}$  and  $SLC7A11^{sut/sut}$  mice**

$SLC7A11^{+/+}$  (+/+; closed circles,  $n = 27$ ) and  $SLC7A11^{sut/sut}$  ( $sut/sut$ ; open circles,  $n = 18$ ) mice were administered 35 mg/kg PTZ (i.p.) once daily for 21 days or until the mouse became kindled. Five separate experiments were performed over 24 months.

**A) Kindling acquisition:** Each data point represents the percentage of mice kindled each day over the 21 day paradigm, which was determined by dividing the number of animals defined as kindled (see methods) by the total number of animals injected. Fractions represent the proportion of mice kindled at the end of the protocol. The rate and proportion of  $SLC7A11^{sut/sut}$  mice that kindled is significantly decreased as compared to  $SLC7A11^{+/+}$  littermate controls as denoted by the large and small asterisk, respectively (\* $p = 0.02$ , log-rank test; # $p = 0.047$ , Fisher's exact test).

**B) Convulsive seizure latency:** Each data point [closed black circles (+/+) or open circles ( $sut/sut$ )] represents the latency to convulsion (behavioral score  $\geq 3$ ) of a single mouse for each of the three consecutive convulsions (depicted as Convulsion 1-3) that led to its kindled state. Bars represent the mean latency to convulsive seizure for each genotype. Kindled  $SLC7A11^{+/+}$  and  $SLC7A11^{sut/sut}$  mice have similar convulsive seizure latencies ( $p = 0.40$ , two-way ANOVA).

between the genotypes ( $431 \pm 45$  vs.  $416 \pm 51$  s for *SLC7A11*<sup>+/+</sup> vs. *SLC7A11*<sup>sut/sut</sup>, respectively;  $p = 0.85$ , unpaired *t* test).

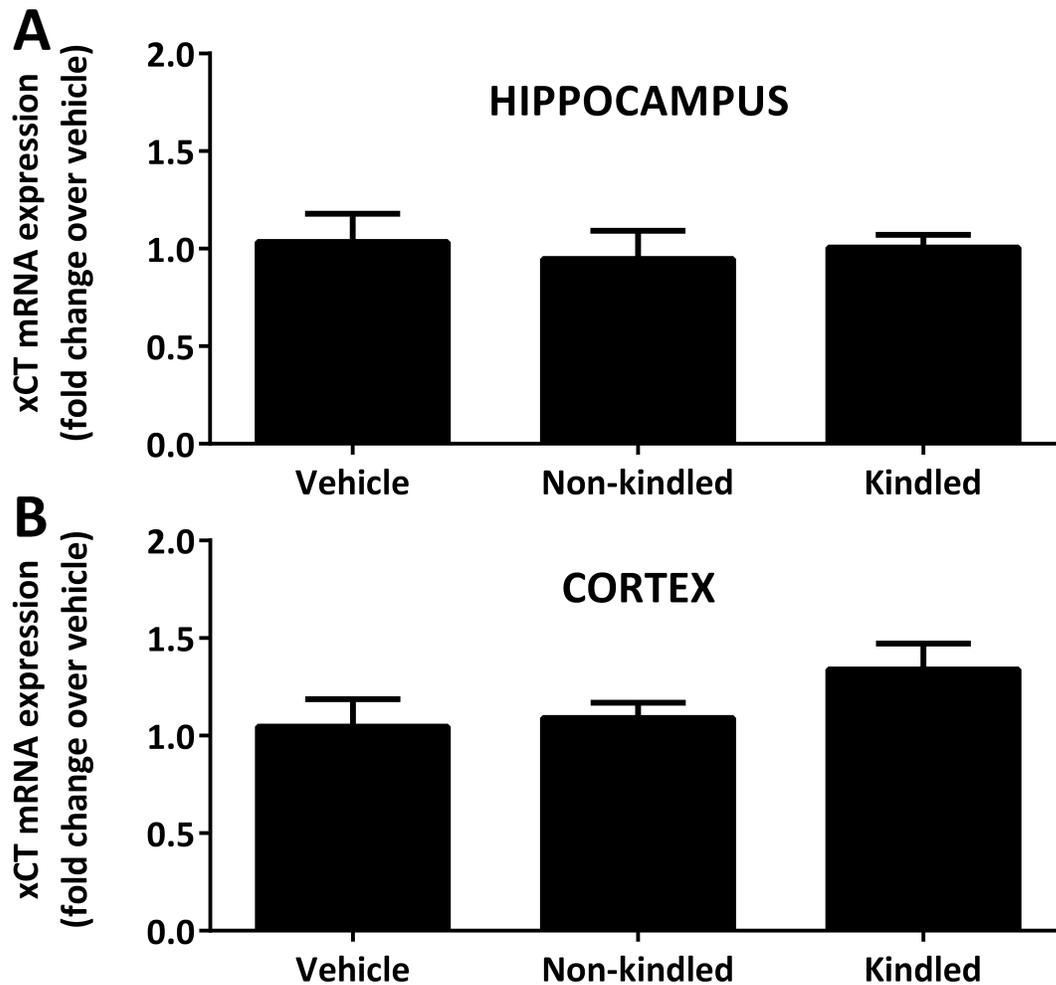

Of note, no mortality occurred in either group during the kindling paradigm. Mice that completed the paradigm exhibited an average weight loss of 0.28 g. However, the final weight of kindled mice did not differ between genotypes ( $25.2 \pm 0.4$  vs.  $23.9 \pm 0.5$  g for *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup>, respectively), nor did these differ from that of non-kindled mice ( $23.2 \pm 1.1$  vs.  $24.4 \pm 0.5$  g for *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup>, respectively, two-way ANOVA).

### ***xCT mRNA levels***

To determine whether the kindling phenotype was associated with an increase in xCT expression, we measured hippocampal and cortical xCT mRNA levels in kindled, non-kindled, and saline-injected *SLC7A11*<sup>+/+</sup> mice via quantitative PCR one day following the final PTZ or saline injection. Neither hippocampal nor cortical xCT mRNA expression levels of kindled mice differed from non-kindled or saline-administered control mice (Figure 3.2), suggesting that basal levels of  $Sx_c^-$  are sufficient to facilitate kindling.

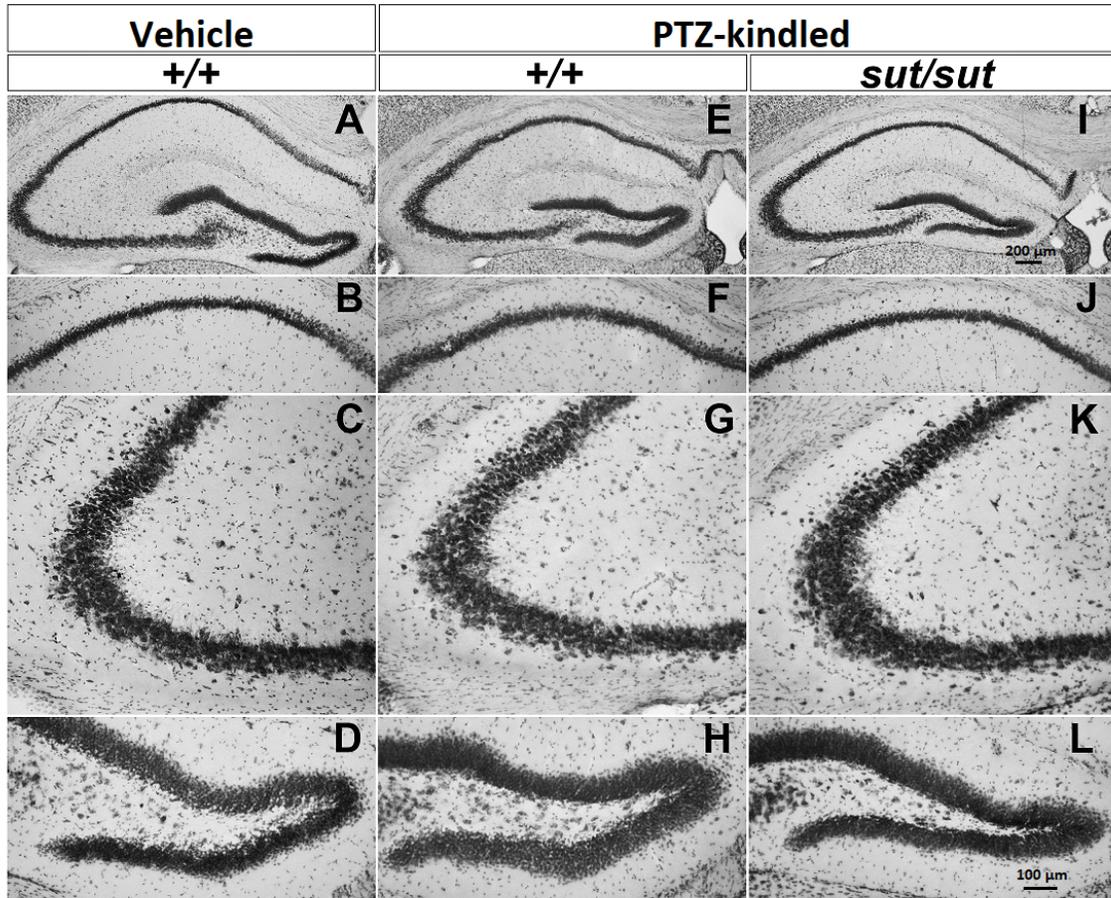

### ***Histological analysis of injury and axonal sprouting***

Sixteen to seventeen days following PTZ-kindling, brains were examined for signs of overt cellular degeneration. Thionin-staining of brain slices revealed that the cortex (not shown) and principal layers of the hippocampal formation (Fig. 3.3A, E, I),

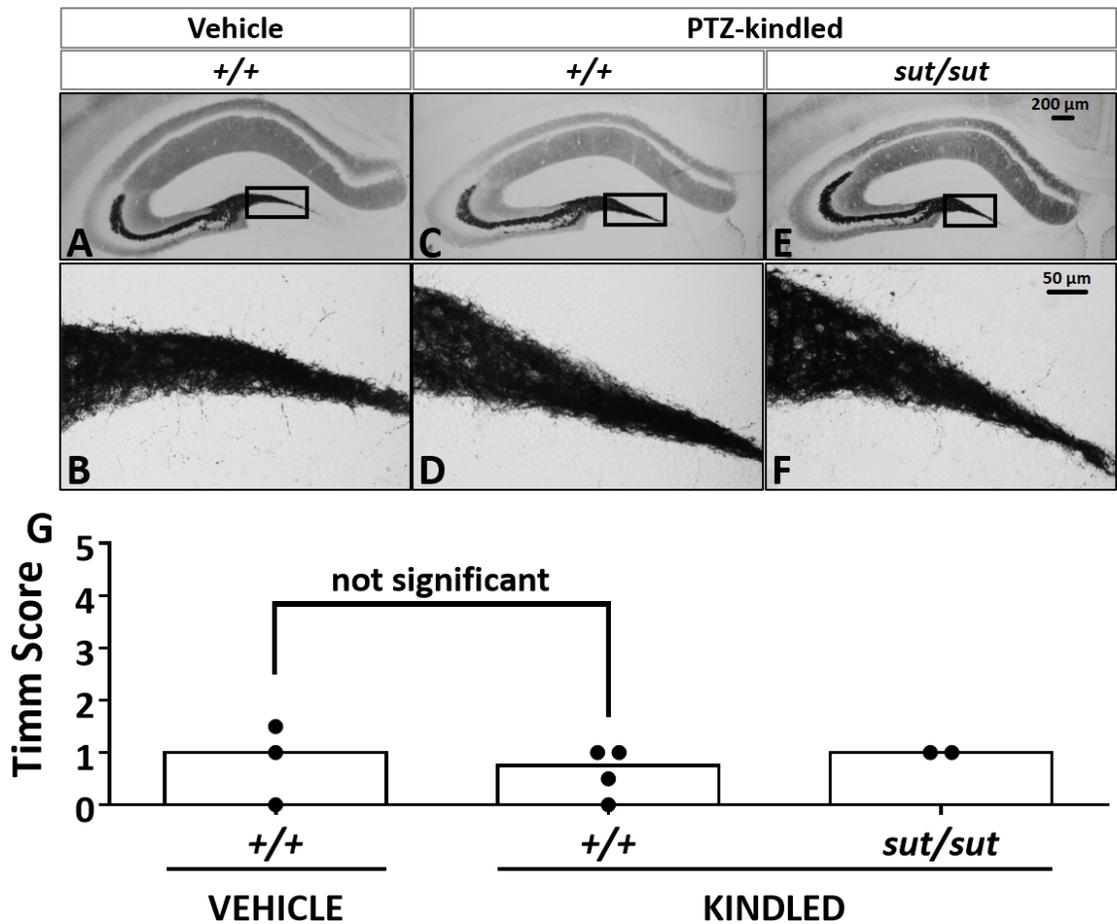

**Figure 3.2 PTZ kindling phenotype is not associated with alterations in xCT mRNA**

*SLC7A11*<sup>+/+</sup> mice on a C57BL/6J background were administered 39 mg/kg PTZ once daily for 21 days or until kindled. Mice receiving vehicle (saline) were injected in parallel. A) The left hippocampus and (B) left cortex were harvested 24 hours following the final injection of PTZ or vehicle and xCT mRNA assessed via qPCR. Data are expressed as mean  $\pm$  SEM fold change in xCT mRNA compared with vehicle-injected controls. No significant between-group differences in xCT mRNA expression in hippocampus ( $p = 0.84$ ) or cortex ( $p = 0.26$ ) was found as determined by one-way ANOVA.  $N = 4-5$  each per treatment group.

**Figure 3.3 PTZ kindling phenotype is not associated with cellular degeneration**

Representative photomicrographs of thionin-stained coronal brain sections  $\approx -1.82$  mm posterior to bregma: (A-D) vehicle (saline)-injected *SLC7A11*<sup>+/+</sup> (+/+; n = 3), (E-H) kindled *SLC7A11*<sup>+/+</sup> (+/+; n = 4), and (I-L) kindled *SLC7A11*<sup>*sut/sut*</sup> (*sut/sut*; n = 2) brain sections. Images represent the hippocampal formation (A, E, I; 8x), CA1 (B, F, J; 20x), CA3 (C, G, K; 20x), or the DG (D, H, L; 20x).

**Figure 3.4 PTZ kindling phenotype is not associated with increased mossy fiber sprouting**

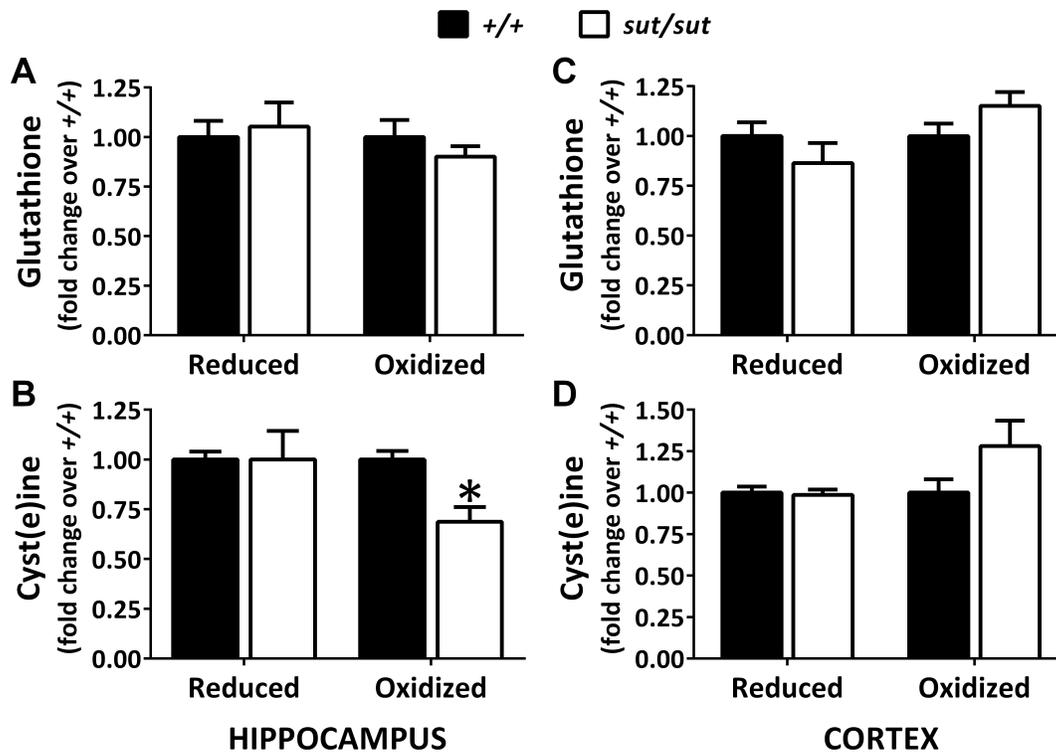

**A-F)** Representative photomicrographs of Timm stained hippocampal formation  $\approx -1.94$  mm posterior to bregma: (A-B) vehicle (saline)-injected control *SLC7A11*<sup>+/+</sup> (+/+; n = 3), (C-D) kindled *SLC7A11*<sup>+/+</sup> (+/+; n = 4) (C-D), and (E-F) kindled *SLC7A11*<sup>*sut/sut*</sup> (*sut/sut*; n = 2). Images represent the hippocampal formation (A, C, E; 8X) and the DG (B, D, F; 40X). Boxes in A, C, and E depict the region of the DG assessed for mossy fiber sprouting.

**G)** Each closed circle represents the Timm score (see methods) of a single mouse determined by calculating the median of the scores assigned to the right and left DG (40x) at  $\approx -1.94$  mm bregma. Open bars represent the median Timm score for each group. There was no significant difference in mossy fiber sprouting between vehicle-injected *SLC7A11*<sup>+/+</sup> and kindled *SLC7A11*<sup>+/+</sup> mice as determined by the Mann-Whitney U test ( $p = 0.69$ ).

including the CA1 (Fig. 3.3B, F, J), the CA3 (Fig. 3.3C, G, K), and the dentate gyrus (DG; Fig. 3.3D, H, L) of kindled mice appeared grossly normal and intact irrespective of genotype. The lack of degeneration was confirmed in adjacent sections using Fluoro Jade C and a 4',6-Diamidino-2-Phenylindole, Dilactate (DAPI) counterstain (data not shown). Aberrant sprouting of DG granule cell axons, known as mossy fiber sprouting, is a common feature in temporal lobe epilepsy and is found in some, but not all, rodent models of epileptogenesis. PTZ-kindled *SLC7A11<sup>+/+</sup>* mice, maintained on a C3H/HeSnJ background, had few mossy fiber synaptic terminals as evidenced by little to no Timm granules in the supragranular layer of the DG that were comparable in number to those quantified in saline-treated control mice (Fig. 3.4; median Timm score = 0.75 vs. 1, respectively;  $p = 0.69$ , Mann Whitney U test). *SLC7A11<sup>sut/sut</sup>* kindled mice also showed little to no change in mossy fiber sprouting (Fig 3.4; median Timm score = 1). Thus, alterations in mossy fiber sprouting cannot explain the reduction in kindling acquisition in *SLC7A11<sup>sut/sut</sup>* as compared to *SLC7A11<sup>+/+</sup>* mice.

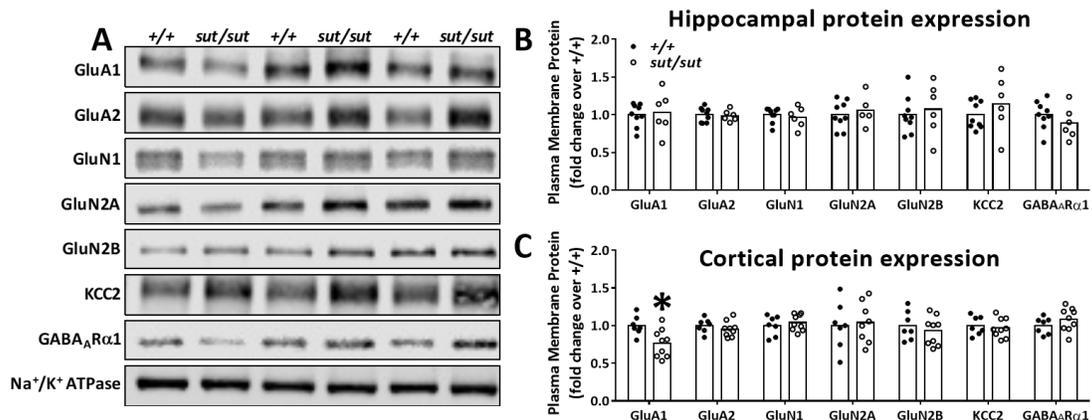

### ***Redox signaling***

Cys derived from  $Sx_c^-$  import of CySS is the rate-limiting substrate for the production of the low molecular weight thiol GSH and contributes to the Cys/CySS redox couple across the cell plasma membrane (Banjac et al 2008, Dringen 2000, Lu 2009). To determine whether loss of  $Sx_c^-$  resulted in a redox imbalance in *SLC7A11<sup>sut/sut</sup>* brains, the hippocampal and cortical levels of reduced and oxidized GSH (GSH and GSSG) and Cys (Cys and CySS) were measured and compared to levels measured

**Figure 3.5 Comparison of redox couples in *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> mice**

The concentration of reduced and oxidized glutathione (GSH and GSSG) or cysteine (Cys and CySS) was determined by high performance liquid chromatography (HPLC) in hippocampus (A-B) or cortex (C-D) of naïve *SLC7A11*<sup>+/+</sup> (*+/+*; n = 8-10) and *SLC7A11*<sup>sut/sut</sup> (*sut/sut*; n = 10) littermates. Bars represent the mean  $\pm$  SEM fold-change over control (*+/+*, set to one) of the concentration of hippocampal or cortical GSH (A, C; left bars), GSSG (A, C; right bars), Cys (B, D; left bars), or CySS (B, D; right bars). Comparisons between individual levels of reduced or oxidized GSH or Cys were made using an unpaired *t* test on raw data. An asterisk (\*) represents a significant between group difference ( $p = 0.002$ ).

**Figure 3.6 Comparison of plasma membrane protein expression in *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> mice**

Plasma membrane protein levels in hippocampus or cortex derived from *SLC7A11*<sup>+/+</sup> (+/+) or *SLC7A11*<sup>sut/sut</sup> (*sut/sut*) littermates were compared using Western blot analysis (see methods). Representative Western blots of +/+ and *sut/sut* hippocampal plasma membrane proteins are shown in (A). Each data point [closed black circles (+/+; n = 7-9) or open circles (*sut/sut*; n = 5-9) represents the level of hippocampal (B) or cortical (C) protein following normalization to their respective loading control (i.e., Na<sup>+</sup>/K<sup>+</sup> ATPase levels). Bars indicate the mean fold change over control (+/+), which was set to one. Hippocampal or cortical plasma membrane protein expression levels were compared using an unpaired *t* test on log-transformed data. An asterisk (\*) represents a significant between group difference (*p* = 0.01).

from *SLC7A11*<sup>+/+</sup> tissues. Neither hippocampal nor cortical GSH (Fig. 3.5A left;  $p = 0.74$ ; Fig. 3.5C left;  $p = 0.28$ , unpaired  $t$  test) nor GSSG (Fig. 3.5A right;  $p = 0.34$ ; Fig. 3.5C right;  $p = 0.12$ , unpaired  $t$  test) levels were different between *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> mice. Cortical levels of Cys were also similar between the genotypes (Fig. 3.5D left;  $p = 0.80$ , unpaired  $t$  test), while there was a small, but non-significant, increase in CySS (Fig. 3.5D right;  $p = 0.12$ , unpaired  $t$  test). Notably, in the hippocampus, the level of CySS was significantly decreased in *SLC7A11*<sup>sut/sut</sup> mice as compared to *SLC7A11*<sup>+/+</sup> littermate controls (Fig. 3.5B right;  $p = 0.002$ , unpaired  $t$  test), while Cys levels were unchanged (Fig. 3.5B left;  $p = 1.00$ , unpaired  $t$  test).

### ***Plasma membrane protein expression levels***

Finally, we assessed cortical and hippocampal surface expression of AMPA (GluA1, GluA2), NMDA (GluN1, GluN2A, and GluN2B), and GABA (GABA<sub>A</sub>R $\alpha$ 1) receptor subunits, as well as, the K<sup>+</sup>/Cl<sup>-</sup> co-transporter (KCC2) (Figure 3.6), as aberrations in plasma membrane levels of each has been associated with abnormal neuronal synchronization (Kelley et al 2016, Mathern et al 1998, Raol et al 2006). Western blot analysis of this suite of plasma membrane proteins revealed no change in expression levels between *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> littermates in the hippocampus (Fig. 3.6A,B). Of note, cortical levels of the AMPA receptor subunit GluA1 were significantly decreased in *SLC7A11*<sup>sut/sut</sup> mice as compared to *SLC7A11*<sup>+/+</sup> littermate controls (Fig. 3.6C;  $p = 0.01$ , unpaired  $t$  test on log transformed data). No other cortical plasma membrane proteins were altered in *SLC7A11*<sup>sut/sut</sup> as compared to *SLC7A11*<sup>+/+</sup> littermate controls (Figure 3.6C).

### 3.5 Discussion

By virtue of its localization to astrocytes and its role in regulating thiol redox systems as well as ambient extracellular glutamate levels,  $Sx_c^-$  (cystine/glutamate antiporter) contributes importantly to CNS homeostasis. In fact, astrocytic transporters, in general, regulate brain excitatory/inhibitory (E/I) balance by providing neurons with energy substrates, by maintaining ion homeostasis, and by removing excess neurotransmitters from the extracellular space. Dysfunction in any one of these activities can facilitate epileptogenesis [reviewed in (Eid et al 2018)]. In this study, we now provide evidence that  $Sx_c^-$  signaling contributes to epileptogenesis in the PTZ-kindling model of acquired epilepsy (Figure 3.1). These findings complement studies demonstrating an incontrovertible role for  $Sx_c^-$  in glioma-associated epilepsy in both mice and man (Buckingham et al 2011, Robert et al 2015).

While  $Sx_c^-$  has been found to be upregulated in glioma (Yuen et al 2012), we do not find any changes in xCT mRNA expression in PTZ-kindled mice as compared to vehicle-injected controls (Figure 3.2), suggesting that basal levels of  $Sx_c^-$  are sufficient to facilitate PTZ-kindling. Given the lack of reliable commercial antibody for xCT (personal observations and (Van Liefferinge et al 2016)), we cannot rule out the possibility that enhanced transporter trafficking (as has been described in human glioma cells *in vitro* (Chase et al 2013)) or increased transporter kinetics (as demonstrated in rat striatum *in vivo*) occurs in wild-type mice (Baker et al 2002). However, present data suggests that *in vivo* glutamatergic tone — maintained in large part by non-vesicular release of glutamate by  $Sx_c^-$  (De Bundel et al 2011, Massie et al 2011b, McCullagh & Featherstone 2014) — may be enough to dysregulate excitatory signaling in wild-type

mice, as we previously documented in an *in vitro* paradigm of hypoglycemic neuronal cell death (Thorn et al 2015). Leading credence to this interpretation are the findings that a reduction in GABAergic inhibition (Kapur et al 1989a, Kapur et al 1989b) and an increase in extracellular glutamate and glutamate receptor levels (Li et al 2000, Schröder et al 1993) are associated with PTZ-kindling in rodents. Conversely, a decrease in ambient, extracellular glutamate levels has been reported in mice lacking  $Sx_c^-$  (De Bundel et al 2011, Massie et al 2011b, McCullagh & Featherstone 2014). This, together with the reduction in cortical GluA1 AMPA receptor subunit protein expression found herein (Figure 3.6), suggests that glutamatergic signaling may be hypo-functional in the *SLC7A11<sup>sut/sut</sup>* mouse brain in a manner sufficient to reduce PTZ-kindling. In keeping with this idea, long-term potentiation (LTP), which is observed at glutamatergic excitatory synapses in hippocampus and cortex, is also reduced in *SLC7A11<sup>sut/sut</sup>* mice (Li et al 2012). However, it should be noted that enhanced synaptic GluA1 expression has been reported in the CA1 region of the hippocampus of transgenic xCT null mice (Williams & Featherstone 2014), although we found no change in global hippocampal GluA1 levels in *SLC7A11<sup>sut/sut</sup>* mice (Figure 3.6). It is difficult to compare these two studies as our plasma membrane measurements include all hippocampal subregions and would capture receptors of both synaptic and extrasynaptic origin. Nevertheless, a global plasma membrane reduction in cortical GluA1 is interesting given evidence from animal models that block of AMPA receptor signaling is anti-epileptogenic (Kodama et al 1999, Namba et al 1994).

$Sx_c^-$ -mediated CySS import has been demonstrated to be fundamental in maintaining the extracellular and intracellular redox balance (e.g., GSH/GSSG and

Cys/CySS) at least *in vitro* where growth of xCT deficient cells is dependent upon the addition of a reducing agent (Sato et al 2005). Interestingly, dysregulation of glutathione homeostasis is associated with impairment of synaptic strength (Almaguer-Melian et al 2000, Robillard et al 2011) and thus represents another possible explanation for the resistance of *SLC7A11<sup>sut/sut</sup>* mice to PTZ-kindling. However, *SLC7A11<sup>sut/sut</sup>* mice have normal Cys, GSH and GSSG levels in hippocampal and cortical tissue, although hippocampal CySS levels were found to be significantly decreased (Figure 3.4). Our data are in agreement with other studies in transgenic xCT nulls showing normal hippocampal GSH levels as compared to wild-type mice (De Bundel et al 2011). To our knowledge, this study is the first to measure the concentration of GSH in cortex as well as brain cyst(e)ine levels in a mouse null for *Sx<sub>c</sub><sup>-</sup>*. Taken *in toto*, current and previous data in both transgenic xCT nulls and *SLC7A11<sup>sut/sut</sup>* mice suggest these animals must employ compensatory mechanisms (e.g., EAAT3 or the alanine-cysteine-serine transporter [ASCT1/2] as alternative Cys transporters) to sustain GSH levels *in vivo*.

Finally, epileptogenic network sensitization and its resultant E/I imbalance is associated with synaptic reorganization, particularly when hilar neurons in the dentate gyrus are lost (Buckmaster & Dudek 1997, Cavazos & Sutula 1990). This reorganization includes reactive synaptogenesis of granule cell mossy fibers, whose targets have been demonstrated to include both excitatory (Scharfman et al 2003) and inhibitory (Sloviter et al 2006) neurons. However, we found no cellular loss in the hippocampus or cortex of PTZ-kindled mice of either genotype (Figure 3.3). We also did not observe any significant hippocampal mossy fiber sprouting in any group tested, indicating that this structural alteration was not necessary for kindling development. These results are not

unprecedented as previous studies show that rats (Osawa et al 2001) and guinea pigs (Mohapel et al 2000) kindle in the absence of mossy fiber sprouting. Moreover, suppression of reactive sprouting in rats (Longo & Mello 1997) and mice (Buckmaster & Lew 2011) has been demonstrated to be ineffective in preventing epileptogenic neuronal sensitization following chemically-induced status epilepticus.

In sum, our results demonstrate that *SLC7A11<sup>sut/sut</sup>* mice have a reduction in PTZ-kindling acquisition that occurs in association with decreased GluA1 levels. Given the permissiveness of  $Sx_c^-$  signaling to epileptogenesis — both glioma- (Buckingham et al 2011, Robert et al 2015) and PTZ-induced (this study) — we postulate that inhibition of astrocyte  $Sx_c^-$  may represent an alternative therapeutic strategy to modulate excessive glutamatergic signaling in individuals predisposed to developing epilepsy.

**Chapter 4: KA-mediated alterations in excitability in system  $x_c^-$  null mice differ according to dosing paradigm.**

## 4.1 Summary

$Sx_c^-$  null (*SLC7A11<sup>sut/sut</sup>*) mice exhibited hyper-excitability (Chapter 2) or hypo-excitability (Chapter 3) following acute or chronic dosing with PTZ, respectively, which induces seizure activity indirectly via disinhibition. In this chapter, the model-dependency of these findings was explored using KA, a glutamate receptor agonist that directly elicits excitation. Female and male *SLC7A11<sup>sut/sut</sup>* and *SLC7A11<sup>+/+</sup>* littermates were injected with KA once (acute paradigm) or repeatedly (escalated dosing paradigm) and the resulting seizure severity scored on a nine-point behavioral scale. Following the elevated dosing paradigm, brains of *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* mice were evaluated for hippocampal cellular degeneration or for plasma membrane protein levels of glutamate and GABA receptor subunits using Fluoro jade C staining or Western blot analysis, respectively. Our results demonstrate that *SLC7A11<sup>sut/sut</sup>* mice exhibit behavioral hyper-excitability following acute KA administration. In contrast, repeated administration of KA in the elevated dosing paradigm elicits behavioral hypo-excitability in *SLC7A11<sup>sut/sut</sup>* mice, a response opposite to that observed in the vast majority of *SLC7A11<sup>+/+</sup>* littermates who entered into a period of unremitting convulsive seizure activity (status epilepticus). The repeated KA dosing paradigm elicited neural degeneration in a subset of both *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* littermates. However, the hippocampal sub-region predominantly affected differed by genotype, with the CA3 or CA1 sub-region demonstrating degeneration in *SLC7A11<sup>sut/sut</sup>* or *SLC7A11<sup>+/+</sup>* littermates, respectively. Cortical levels of the GABA receptor subunit GABA<sub>A</sub>R $\alpha$  were increased in *SLC7A11<sup>sut/sut</sup>* mice that became hypo-mobile by the end of the repeated dosing paradigm as compared to *SLC7A11<sup>sut/sut</sup>* mice that entered into status epilepticus. No between-genotype differences were found in plasma membrane proteins tested following the repeated KA dosing protocol. These results extend findings in Chapters 2 and 3 and indicate that positive or negative excitability alterations elicited in

*SLC7A11<sup>lut/lut</sup>* mice via acute or repeated/chronic chemoconvulsant administration, respectively, are not model dependent.

## 4.2 Introduction

System  $x_c^-$  ( $Sx_c^-$ ) is a heteromeric amino acid antiporter that exports glutamate and imports cystine with 1:1 stoichiometry (Bannai & Kitamura 1980, Sato et al 1999). In most tissues, including the central nervous system (CNS), cystine import through  $Sx_c^-$  is necessary for the synthesis and maintenance of the cellular antioxidant, glutathione (GSH). This, along with the cysteine/cystine (Cys/CySS) redox cycle, also influenced by  $Sx_c^-$  activity, contributes to the intracellular/extracellular redox homeostasis (Banjac et al 2008, Sato et al 2005).  $Sx_c^-$  is also an important contributor to the ambient extracellular glutamate levels that bathe the CNS *in vivo* (Augustin et al 2007, Baker et al 2002, De Bundel et al 2011, Massie et al 2011b, Melendez et al 2005). Studies addressing the cellular source of this glutamate conclude that it is astrocyte-derived (Augustin et al 2007, Grosjean et al 2008, Warr et al 1999).

Data presented in Chapter 2 of this dissertation demonstrated that *SLC7A11<sup>sut/sut</sup>* mice — who harbor a natural mutation in exon 12 of *SLC7A11*, rendering them null for the  $Sx_c^-$  substrate specific light chain xCT (Chintala et al 2005) — are more excitable (i.e., have lower convulsive seizure thresholds) than *SLC7A11<sup>+/+</sup>* littermate control mice following acute challenge with the GABA<sub>A</sub> receptor antagonist PTZ (Fig 2.9). Despite this, *SLC7A11<sup>sut/sut</sup>* mice show behavioral signs of hypoexcitability upon chronic administration of PTZ. Specifically, data presented in Chapter 3 established that repeated daily injections of a kindling dose of PTZ ultimately leads to a permanent decrease in the threshold of excitability in *SLC7A11<sup>+/+</sup>* mice (i.e., mice become kindled), whereas the percent *SLC7A11<sup>sut/sut</sup>* mice that kindle over the same 21 days is

significantly lower (Fig 3.1). These data suggest that  $Sx_c^-$  activity modulates synaptic strength *in vivo* in a context-dependent manner.

In contrast to our findings using PTZ – whereby excitation results from endogenous glutamate signaling – transgenic xCT null mice on a C57BL/6 background appear to have an elevated seizure threshold in response to three pharmacologically distinct chemoconvulsants (De Bundel et al 2011). Specifically, xCT null mice require an elevated dose of either the muscarinic acetylcholine agonist, pilocarpine, or the glutamate receptor agonist, KA, to elicit the same behavioral seizure response as wild-type controls (De Bundel et al 2011). Furthermore, this study demonstrated that xCT null mice exhibit decreased seizure severity and mortality, as well as increased latency to seize, in response to a systemic injection of the glutamate receptor agonist NMDA (De Bundel et al 2011). Thus, contrary to our findings using the *SLC7A11<sup>sut/sut</sup>* mice in the acute PTZ paradigm (Chapter 2), these results suggest that xCT null mice on the C57BL/6 background have an elevated seizure threshold.

The goal of this study was to determine if our findings using PTZ in the *SLC7A11<sup>sut/sut</sup>* mice were model-dependent. As such, the susceptibility of *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* littermates to seizures evoked by acute or repeated administration of the glutamate receptor agonist KA was explored. Whether KA induced neural degeneration or altered plasma membrane protein expression levels was also explored given the association of these phenotypes with KA-mediated excitotoxic cell death (Nadler et al 1980) or neuronal synaptic strength, respectively (Mathern et al 1998, Raol et al 2006).

## 4.3 Materials and Methods

### 4.3.1 Animals

Mice were maintained in the AALAC accredited Laboratory Animal Resource facility of Syracuse University on a 12 hr light/dark schedule (7am/7pm). Standard mouse chow and water were provided *ad libitum*. Experiments were carried out using male and female mice (8-12 weeks old) in accordance with the National Institutes of Health guidelines for the use of experimental animals as approved by the Institutional Animal Care and Use Committee of Syracuse University. Wild-type ( $SLC7A11^{+/+}$ ) and xCT mutant ( $SLC7A11^{sut/sut}$ ) mice were bred in-house from heterozygous ( $SLC7A11^{+/sut}$ ) breeding units (F1) that were obtained by crossing  $SLC7A11^{sut/sut}$  male mice (JAX, Stock #001310) with  $SLC7A11^{+/+}$  female C3H/HeSnJ mice (JAX, Stock #000661). F2  $SLC7A11^{+/sut}$  progeny were also used as breeding units for studies. Genotyping was performed via PCR analysis of tail genomic DNA samples:  $+/+$  primers, 5'- GAA GTG CTC CGT GAA GAA GG -3' (forward), 5'- ATC TCA ATC CTG GGC AGA TG -3' (reverse);  $sut/sut$  primers, 5'- CCA CTG TTG TAG GTC AGC TTA GG -3' (forward), 5'- CAG GAC CTG TGA ATA TGA TAG GG -3' (reverse). Mice were segregated by sex at weaning and placed two to three per cage such that at least one mouse of each genotype was represented. These breeding and housing strategies were employed to control for environmental differences, genetic background influences, and genetic drift (Barnwell et al 2009, Pick & Little 1965).

### **4.3.2 KA dosing paradigms**

Changes in *in vivo* network excitability were provoked in *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>mut/mut</sup>* mice by injection of KA (Abcam, Cambridge, U.K.). Mice were acclimated to handling by performing mock daily intraperitoneal (i.p.) injections five days prior to each study, which consisted of inverting the mouse and rubbing its abdomen. They were also acclimatized to the procedure room for at least one hour prior to experimentation. The KA injection solution (1 – 1.5 mg/mL) was prepared fresh on day of use in 0.05M phosphate buffered saline (PBS) and filter sterilized prior to i.p. administration.

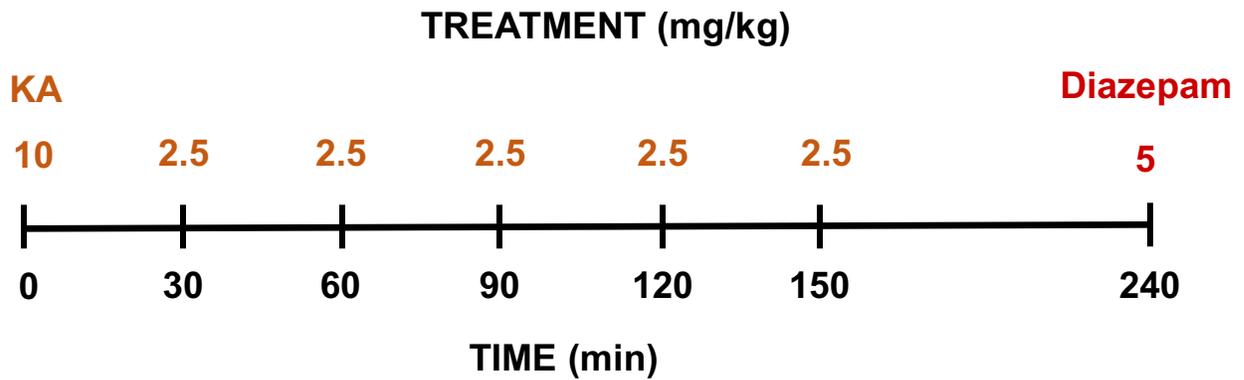

#### **4.3.2.1 Acute Dose**

*SLC7A11<sup>+/+</sup>* or *SLC7A11<sup>mut/mut</sup>* mice were injected once with KA (12 mg/kg, males; 15 mg/kg, females) in a volume of 10 ml/kg body weight. Following the injection, mice were monitored for 30 min and the time and severity of behavioral seizures scored and recorded by an observer blinded to genotype using a nine-point modified Racine scale as described below. All mice received 5mg/kg diazepam (i.p., dissolved in 0.9% saline containing 40% propylene glycol) 60 min after dosing to arrest any ongoing seizure activity.

#### **4.3.2.2 Escalating Dose**

The escalating dosing paradigm was initiated by injecting *SLC7A11<sup>+/+</sup>* or *SLC7A11<sup>mut/mut</sup>* mice with a loading dose of 10 mg/kg KA in a volume of 10 ml/kg body weight. Booster doses of 2.5 mg/kg KA were administered 30, 60, 90, 120, and 150 min later (see below) in a volume of 2.5 ml/kg body weight. Mice were continuously monitored throughout the 240 min paradigm and the time and severity of behavioral

seizures scored and recorded by an observer blinded to genotype using a nine-point modified Racine scale as described in Section 4.3.2.3 (Table 4.1). All mice received 5mg/kg diazepam (i.p., dissolved in 0.9% saline containing 40% propylene glycol) 240 min after the initial dose of KA to arrest any on-going seizure activity.

#### 4.3.2.3 Quantification of KA-induced Seizure Behavior

Behavioral seizure scores were recorded for each mouse by an observer blinded to genotype to ensure unbiased scoring (see Table 4.1 below). Scores  $\leq 4$  = non-convulsive seizures; scores  $\geq 5$  = clonic/convulsive seizure.

***Table 4.1: Descriptive KA-induced Seizure Scoring System***

<b>Seizure Score</b>	<b>Abbreviated Description</b>	<b>Detailed Description</b>
0	Normal behavior	Normal ambulation/exploration: sniffing, rearing, grooming, eating, digging, and climbing are common. Unless sleeping, mice will rarely be motionless for more than a few seconds.
1	Hypomobility and hypoactivity	Overall behavior will be dominated by bouts (> 10 sec in duration) of staring and motionlessness that may be interrupted by brief sniffing or ambulation.
2	Hyperactivity	Hyperactivity includes excessive unidirectional rotations, escape-like behavior, and running with an abnormal gait. This generally follows periods of hypoactivity.
3	Repeated twitching or myoclonus	Animal with normal posture exhibiting two or more brief ( $\leq 2$ sec) myoclonic twitches of head, tail or axial musculature. Twitching of whiskers and facial movements are apparent.
4	Rearing without clonus	Animal adopts a posture with prominent kyphosis. Head bobbing or nodding may occur, but movement is not clonic.
5	Rearing with clonus	Similar to score 4 with addition of clonic movement of one or both paws/forelimbs. Animal may transiently lose balance but never falls on side. Continuous clonic movements lasts $\leq 10$ min.
6	Generalized seizure with righting reflex	Animals start showing generalized convulsive seizures but will not lose their righting reflex. Convulsive seizures rarely last longer than 1 min.
7	Generalized seizure with loss of righting or violent jumping	Similar to score 6, but animal will fall on side for $\geq 5$ seconds due to hind and forelimb clonus. Animal may barrel roll or violently jump (popcorn) and run around cage.
8	Status Epilepticus, continuous generalized seizure activity	Sustained score 5-7 seizures for $\geq 20$ min. Typically, score 5 seizures evolve to score 6-7 and resolve back to score 5 without any intervening periods of absent convulsive seizure activity or lesser seizure scores. Clonic seizures involving loss of posture may proceed uninterrupted for tens of minutes.

Table adapted from descriptions in (Ferraro et al 1999, Pitkanen 2006, Racine 1972).

### **4.3.3 Histology**

*SLC7A11<sup>+/+</sup>* or *SLC7A11<sup>sut/sut</sup>* mice administered 22.5 mg/kg KA (escalated dosing paradigm) were sacrificed 72 hr later by transcardial perfusion and fixation with ice-cold 1x PBS and 4% paraformaldehyde (PFA) in PBS. Following removal from the cranium, brains were post-fixed in 4% PFA in PBS for 24 hr (4°C), transferred to a 20% sucrose solution for 24 hr (4°C), and then snap-frozen on dry ice in Optimal Cutting Temperature (O.C.T.) compound (Tissue-Tek, Torrance, CA) prior to storage at -80°C. Frozen brains were cut serially ( $\approx$ -0.94 – -2.46 mm posterior to bregma) into 14  $\mu$ m coronal sections, mounted on SuperFrost Plus slides (Fisher Scientific, Houston, TX), air dried at room temperature for 24 hours, and then stored at -20°C until processing.

#### *4.3.3.1 Thionin staining*

Frozen sections were removed from -20°C and initially incubated in a descending ethanol series of 70% (five min) and 50% (one min) ethanol followed by a one min rinse in deionized (DI) water prior to incubation in 0.5% thionin (Sigma Chemical Co., St Louis, MO) for 10 min. Slides were rinsed in DI water 2x for one min each followed by serial dehydration in absolute ethanol (70%, 95%, 100%, 100%; one min each). Ethanol was cleared with xylenes (2x for one or three min each), after which coverslips were mounted using Permount mounting media.

#### *4.3.3.2 Fluoro Jade C staining*

Tissue sections within 168  $\mu$ m of those processed for thionin staining were Fluoro Jade C stained (AAT Bioquest, Sunnyvale, CA). Frozen sections were removed from -20°C and dried at 50-60°C for 25-30 min. Samples were initially incubated with basic alcohol solution (1% NaOH in absolute ethanol) for 5 min followed by 70% ethanol

for 2 min and a 2 min rinse in deionized (DI) water. Sections were then placed in 0.06% potassium permanganate for 10 min, rinsed in DI water for 2 min, and then placed in 0.0001% Fluoro Jade C in 0.1% acetic acid for 10 min. Samples were rinsed in DI water 3X for 1 min each, dried on a slide warmer at 50-60°C, and images captured with a Zeiss Axio Imager A2 microscope equipped with epifluorescence and an AxioCam MRc digital camera (Carl Zeiss, Germany). Following image acquisition, samples were cleared with xylenes and mounted with DPX mounting media. All images were processed identically using Zen Microscope and Imaging Software (Carl Zeiss, Germany, RRID: SCR\_013672) and Microsoft PowerPoint.

#### **4.3.4 Immunoblotting**

##### *4.3.4.1 Plasma membrane protein isolation*

A separate cohort of *SLC7A11<sup>+/+</sup>* or *SLC7A11<sup>mut/mut</sup>* mice having undergone the escalating KA dosing paradigm were perfused transcardially with ice-cold 1x PBS under full anesthesia within 5-25 min of diazepam injection. Cortices were dissected, snap frozen in liquid nitrogen, and stored at -80°C prior to use. Plasma membrane proteins were isolated from bilateral cortices (one mouse/sample) using an aqueous two-phase separation method as per manufacturer's instructions (Plasma Membrane Protein Extraction Kit, Abcam, Cambridge, U.K.). Isolated proteins were suspended in 0.5% Triton X-100 in PBS. Samples were stored at -80°C until immunoblotting. Protein concentrations were quantified using the BCA assay kit (Pierce, Rockford, IL).

#### *4.3.4.2 Gel electrophoresis and protein detection*

Protein samples (7.5 µg) were separated by 8% SDS-PAGE under reducing (10mM dithiothreitol) and chaotropic (8M urea) conditions followed by electrophoretic transfer to a PVDF membrane (Bio-Rad; Hercules, CA). Membranes were blocked for one hr at room temperature (Odyssey® blocking buffer, LI-COR Biosciences; Lincoln, NE) then probed overnight (4°C) with the following antibodies: anti-Na<sup>+</sup>/K<sup>+</sup> ATPase α1 mouse monoclonal antibody (1:750; Abcam; RRID: AB\_306023); anti-GluA1 rabbit polyclonal antibody (1:750; Abcam; RRID:AB\_2113447); anti-GluA2 rabbit polyclonal antibody (1:750; Abcam; RRID:AB\_2232655); anti-GluN1 rabbit monoclonal antibody (1:750; Cell Signaling; RRID: AB\_1904067); anti-GABA<sub>A</sub>Rα1 rabbit polyclonal antibody (1:3000; Abcam; RRID: AB\_732498). Species-specific secondary antibodies labeled with spectrally distinct IRDye® fluorescent dyes (LI-COR Biosciences, Lincoln, NE) were used to detect primary antibodies (1 hr at 25°C) (1:10,000 dilution). Results were recorded on a LI-COR ODYSSEY® Fc Imaging system (LI-COR Biosciences; Lincoln, NE) and protein levels quantified using Image Studio 3.1 (LI-COR Biosciences; Lincoln, NE). Each protein was normalized to the Na<sup>+</sup>/K<sup>+</sup> ATPase (males) or total protein (females) levels contained in each lane. The signal intensity pertaining to the amount of cortical protein per lane (7.5 µg) was determined to be in the linear range for each antibody at their respective dilution (data not shown).

#### **4.3.5 Statistical analysis**

All statistical analyses were performed using GraphPad Prism (Version 6.0.1, Graphpad Software, Inc., La Jolla, CA). Acute seizure severity and proportions

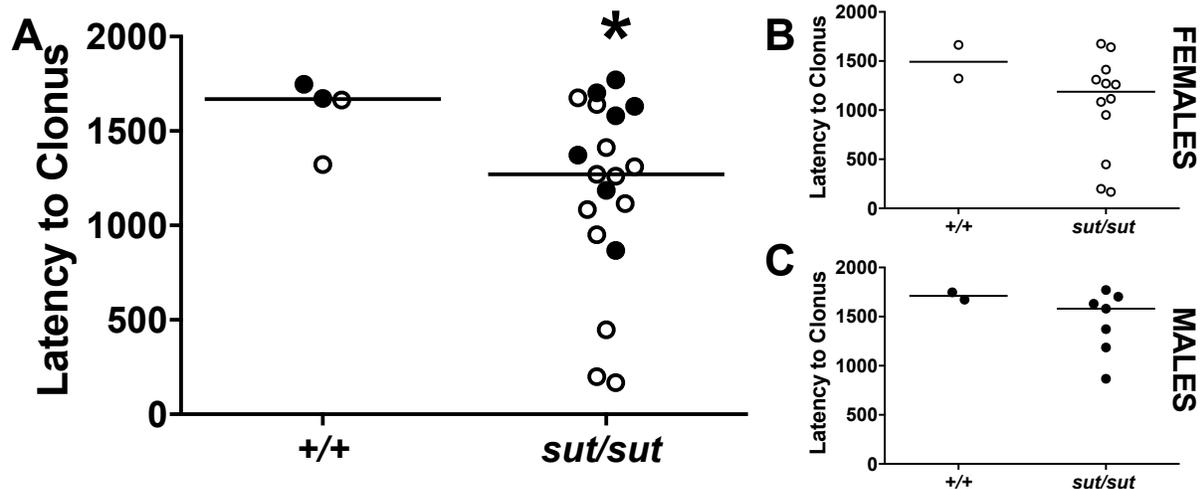

indicating the percent of mice convulsing were compared using a Mann-Whitney U test and Fisher's exact test, respectively. An unpaired *t* test with Welch's correction was used to compare latency to seizure. Curves depicting the median seizure scores over time were compared using a comparison of fit test, while individual seizure scores over time were compared using the Kruskal-Wallis test. Kaplan Meier survival curves were compared using the Mantel-Cox log-rank test. Prior to parametric analysis, immunoblot data was log transformed ( $y = \log(y+1)$ ) and compared using two-way ANOVA. In all cases, significance was set at  $p < 0.05$ .

#### 4.4 Results

##### ***Acute KA-induced seizure severity***

The behavioral seizure severity in response to a single acute dose of KA (12-15 mg/kg) was compared in *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* mice. Irrespective of genotype or sex, within minutes of receiving the dose of KA, all mice exhibited a decrease in spontaneous locomotor activity (seizure score = 1). This behavior was often followed by hypermobility, manifest by excessive pacing, climbing, or unilateral rotations (seizure score = 2), or sporadic myoclonic twitches (seizure score = 3). In a subset of mice, behavioral seizures progressed to a kyphosis, or hunchback, posture (seizure score = 4). The majority of *SLC7A11<sup>sut/sut</sup>* (19/20), and a subset of *SLC7A11<sup>+/+</sup>* mice (4/17), progressed to behavioral clonic or convulsive seizures manifest by kyphosis with forelimb clonus (seizure score = 5), a generalized convulsion (seizure score = 6), or a generalized convulsion with loss of righting reflex and/or violent jumping (seizure score

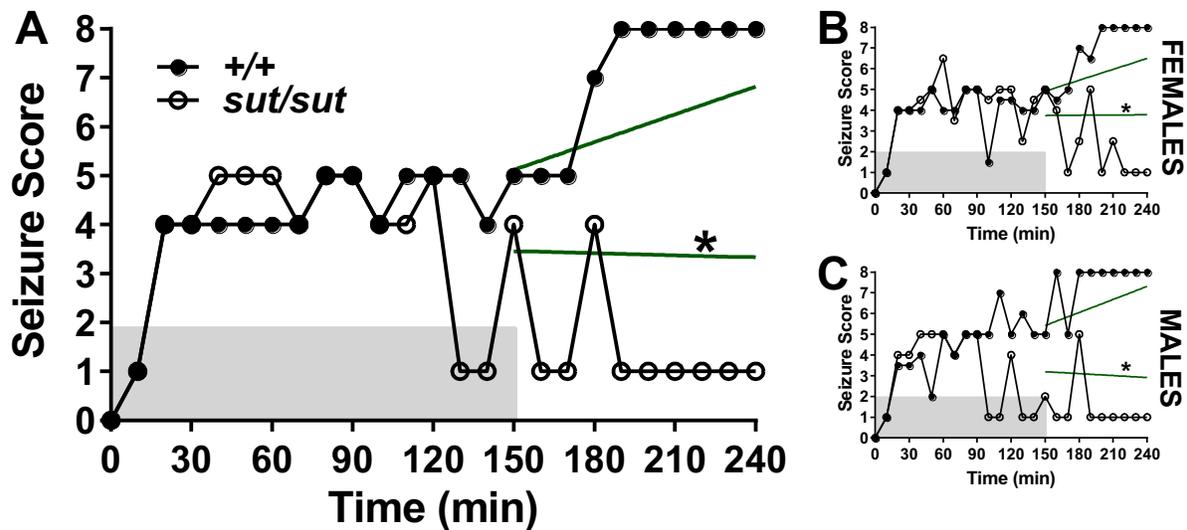

**Figure 4.2 Comparison of convulsive seizure latency between  $SLC7A11^{+/+}$  and  $SLC7A11^{sut/sut}$  mice**

The latency to convulsion of  $SLC7A11^{+/+}$  (+/+, n = 4; 2M, 2F) and  $SLC7A11^{sut/sut}$  (sut/sut, n = 19; 7M, 12F) mice that achieved a score of  $\geq 5$  in Figure 4.1 is graphed.

**A-C)** Each data point [closed black circles (males) or open circles (females)] represents the latency to convulsion (behavioral score  $\geq 5$ ) of a single mouse during the 30 min observation period: (A) combined males plus females, (B) females, or (C) males only. Bars represent the median latency for each genotype.  $SLC7A11^{sut/sut}$  mice have a decreased convulsive seizure latency as compared to  $SLC7A11^{+/+}$  littermate controls as denoted by the asterisk (A only; \* $p = 0.0346$ , Unpaired  $t$  test with Welch's correction).

= 7). A fraction of *SLC7A11<sup>sut/sut</sup>* mice exhibited unremitting clonic/convulsive seizure activity as evidenced by a score of 5, 6, or 7 for  $\geq 20$  min and as such, these mice were assigned a score of 8 (status epilepticus).

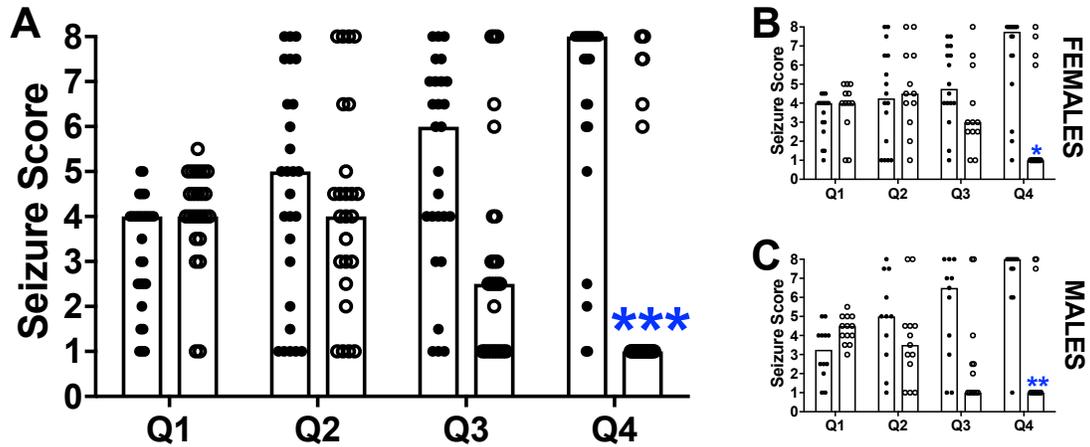

The median seizure score in female and male *SLC7A11<sup>sut/sut</sup>* mice was significantly greater than that of *SLC7A11<sup>+/+</sup>* littermate controls (Fig. 4.1A  $p < 0.0001$ ; Mann-Whitney U test). Stratification of this data by sex revealed that female (Fig. 4.1B;  $p = 0.0002$ ) but not male (Fig. 4.1C;  $p = 0.1142$ ) *SLC7A11<sup>sut/sut</sup>* mice have significantly enhanced seizure severity as compared to *SLC7A11<sup>+/+</sup>* sex-matched littermate controls at their respective KA doses (Mann Whitney U test). Furthermore, a decreased convulsive seizure threshold was evident in the *SLC7A11<sup>sut/sut</sup>* mice, with 95% (19/20) reaching a seizure stage  $\geq 5$ , compared to 23.5% (4/17) of *SLC7A11<sup>+/+</sup>* mice (Fig. 4.1D;  $p < 0.0001$ ; Fisher's exact test). This effect, however, was sex-independent, with 92.3% of female and 100% of male *SLC7A11<sup>sut/sut</sup>* mice experiencing a clonic seizure as compared to 18.2% of female and 33.3% of male *SLC7A11<sup>+/+</sup>* sex-matched littermate controls (Females, Fig. 4.1E,  $p = 0.0005$ ; Males, Fig. 4.1F,  $p = 0.0210$ ; Fisher's exact test). Finally, the mean latency to clonus was decreased in combined female and male *SLC7A11<sup>sut/sut</sup>* mice as compared to *SLC7A11<sup>+/+</sup>* littermate controls (Fig. 4.2A;  $265 \pm 57$  and  $302 \pm 45$  sec, mean  $\pm$  SEM, for *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* mice, respectively,  $p = 0.0346$ , unpaired  $t$ -test with Welch's correction). It is also noteworthy that the latency to clonic seizure was reduced in *SLC7A11<sup>sut/sut</sup>* versus sex-matched *SLC7A11<sup>+/+</sup>* female (Fig. 4.2B;  $1044 \pm 148.5$  s in *SLC7A11<sup>sut/sut</sup>* vs.  $1493 \pm 171$  s in *SLC7A11<sup>+/+</sup>*, mean  $\pm$  SEM) and male (Fig. 4.2C;  $1444 \pm 122.6$  s in *SLC7A11<sup>sut/sut</sup>* vs.  $1711 \pm 37.5$  s in

**Figure 4.3 Comparison of  $SLC7A11^{+/+}$  and  $SLC7A11^{sut/sut}$  seizure severity in the escalating KA dosing paradigm**

Male ( $n = 12$ ) and female ( $n = 16$ )  $SLC7A11^{+/+}$  ( $+/+$ , total  $n = 28$ ) and male ( $n = 13$ ) and female ( $n = 12$ )  $SLC7A11^{sut/sut}$  ( $sut/sut$ , total  $n = 25$ ) littermates underwent the escalating KA dose treatment paradigm and behavioral responses were scored using a 9-point scale as described in the materials and methods. Data were pooled from 9 independent experiments performed over 4 months.

**A-C) Time Course:** The shaded area represents the 150 min interval in which KA was administered. Each data point [closed black circles ( $+/+$ ) or open circles ( $sut/sut$ )] represents the median maximal seizure score obtained: (A) females and males combined, (B) females, or (C) males only for each 10 min interval of the 240 min treatment paradigm. Green linear regression lines are fitted from the last kainate dose ( $t = 150$  min) to the end of the protocol ( $t = 240$  min). Slope of the  $SLC7A11^{sut/sut}$  line is significantly different from slope of the  $SLC7A11^{+/+}$  line as denoted by the asterisk ( $p < 0.0001$ ; Comparison of fit test).

**Figure 4.4 Comparison of individual *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> mouse seizure severity in the escalating KA dosing paradigm**

The individual seizure scores of mice administered KA in Figure 4.3 were compared.

**A-C) Individual seizure scores:** Each data point [closed black circles (*+/+*) or open circles (*sut/sut*)] represents the median seizure score obtained by an individual mouse: (A) females and males combined, (B) females, or (C) males only calculated from the maximal seizure score obtained over the six 10 min intervals contained in each quartile (Q1-Q4). Bars represent the median seizure score for each genotype calculated using the median score from all animals. *SLC7A11*<sup>sut/sut</sup> mice have significantly lower seizure severity in the final 60 min quartile (Q4) of the four hour KA dosing paradigm as compared to *SLC7A11*<sup>+/+</sup> littermate controls as denoted by the asterisk(s) (\* $p < 0.01$ , \*\* $p < 0.001$ , \*\*\* $p < 0.0001$ ; Kruskal-Wallis test).

*SLC7A11*<sup>+/+</sup>, mean ± SEM) littermates, although the sample sizes preclude a sufficiently powered statistical comparison.

### ***Seizure severity in mice administered an escalating dose of KA***

To further explore changes in excitability, mice were administered an escalating dose of KA (22.5 mg/kg over 150 min) (Claycomb et al 2012). Similar to behavioral seizure activity elicited in the acute paradigm, a profound hypomobility was observed in all mice regardless of genotype or sex within minutes of the initial 10 mg/kg dose of KA. As the dosing protocol progressed over the first hour, the median maximal seizure score (MMSS) in the *SLC7A11*<sup>mut/mut</sup> mice reached a score of 5 (kyphosis with forelimb clonus) compared to a score of 4 (kyphosis) in *SLC7A11*<sup>+/+</sup> littermate controls (Fig. 4.3A). However, by the second hour of the protocol (t = 120 min), the behavior of *SLC7A11*<sup>mut/mut</sup> mice was indistinguishable from their *SLC7A11*<sup>+/+</sup> littermate controls (Fig. 4.3A). Interestingly, in the 90 min following the final KA dose (t = 150-240 min), the MMSS trend lines fit to seizure scores in *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>mut/mut</sup> mice began to diverge (green lines on Fig. 4.3A,  $p < 0.0001$ , comparison of fit test). Upon receiving the final dose of KA at t = 150 min, seizure activity in *SLC7A11*<sup>+/+</sup> mice escalated such that the MMSS reached status epilepticus (seizure score = 8) by the final hour of the protocol. Unexpectedly, *SLC7A11*<sup>mut/mut</sup> mice exhibited a striking decrease in behavioral seizure severity within the final hour of the protocol dominated by immobility (seizure score = 1) in the majority of mice. Of note, the aforementioned seizure behaviors occurred independent of sex, with both female (Fig. 4.3B) and male (Fig. 4.3C) *SLC7A11*<sup>mut/mut</sup> mice exhibiting hypomobility in the final quartile of the paradigm as

compared to *SLC7A11<sup>+/+</sup>* sex-matched littermate controls, which were consistently in status epilepticus.

A comparison of the MMSS of individual mice in each quartile of the paradigm further demonstrated the divergence in seizure activity between *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>mut/mut</sup>* mice in the final quartile of the escalating dose protocol. While the median MMSS of the population of male and female (Fig. 4.4A), female (Fig. 4.4B), or male (Fig. 4.4C) *SLC7A11<sup>+/+</sup>* mice was at a seizure score = 8 in the fourth quartile, the median MMSS of the *SLC7A11<sup>mut/mut</sup>* mice was at a seizure score = 1 (Females and males, Fig. 4.4A,  $p < 0.0001$ ; Females, Fig. 4.4B,  $p < 0.01$ ; Males, Fig. 4.4C,  $p < 0.001$ ; Kruskal-Wallis test).

#### ***Incidence of status epilepticus (SE) and fatality in escalated dosing paradigm.***

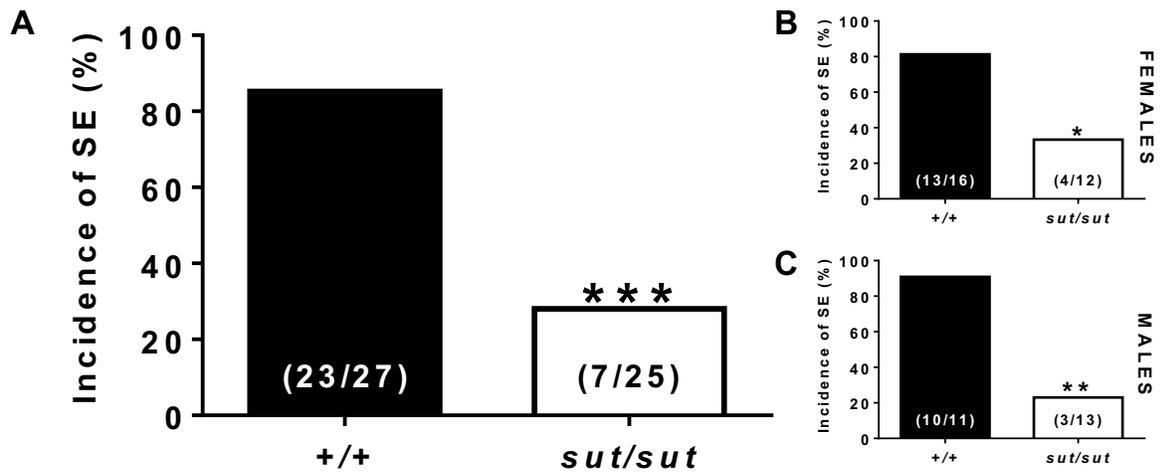

The disparity in behavioral seizure activity induced by an escalating dose of KA was further exemplified by examining the incidence of status epilepticus in quartile four, which was three times greater in *SLC7A11<sup>+/+</sup>* [85.2% (23/27)] as compared to *SLC7A11<sup>mut/mut</sup>* mice [28% (7/25)] (Fig. 4.5A;  $p < 0.0001$ ; Fisher's exact test). This effect was also sex-independent, with 81.3% of female and 91% of male *SLC7A11<sup>+/+</sup>* mice experiencing status epilepticus as compared to 33.3% of female and 23.1% of male *SLC7A11<sup>mut/mut</sup>* sex-matched littermate controls (Females, Fig. 4.5B,  $p = 0.0189$ ; Males, Fig. 4.5C,  $p = 0.0013$ ; Fisher's exact test).

*In toto*, 23% (12/53) of mice administered an escalating dose of KA died over the course of the four-hour paradigm, with all but one of the deaths occurring in the final hour after cessation of the 150 min dosing period (Fig. 4.6). Notably, the majority of

deaths occurred in *SLC7A11*<sup>+/+</sup> mice, with just 64.3% (18/28) of *SLC7A11*<sup>+/+</sup> as compared to 92% (23/25) of *SLC7A11*<sup>sut/sut</sup> mice surviving the paradigm (Fig. 4.6A;  $p = 0.0137$ , Mantel-cox log-rank test). This effect was driven by a decreased incidence of death in *SLC7A11*<sup>sut/sut</sup> male mice relative to *SLC7A11*<sup>+/+</sup> sex-matched controls; 92.3% (12/13) of *SLC7A11*<sup>sut/sut</sup> mice survived the paradigm as compared to 58.3% (7/12) of *SLC7A11*<sup>+/+</sup> mice (Fig. 4.6C;  $p = 0.0402$ ; Mantel-cox log-rank test). A similar decrease in KA-induced mortality, although statistically insignificant (Fig. 4.6B;  $p = 0.1374$ , Mantel-cox log-rank test), was observed in *SLC7A11*<sup>sut/sut</sup> female mice.

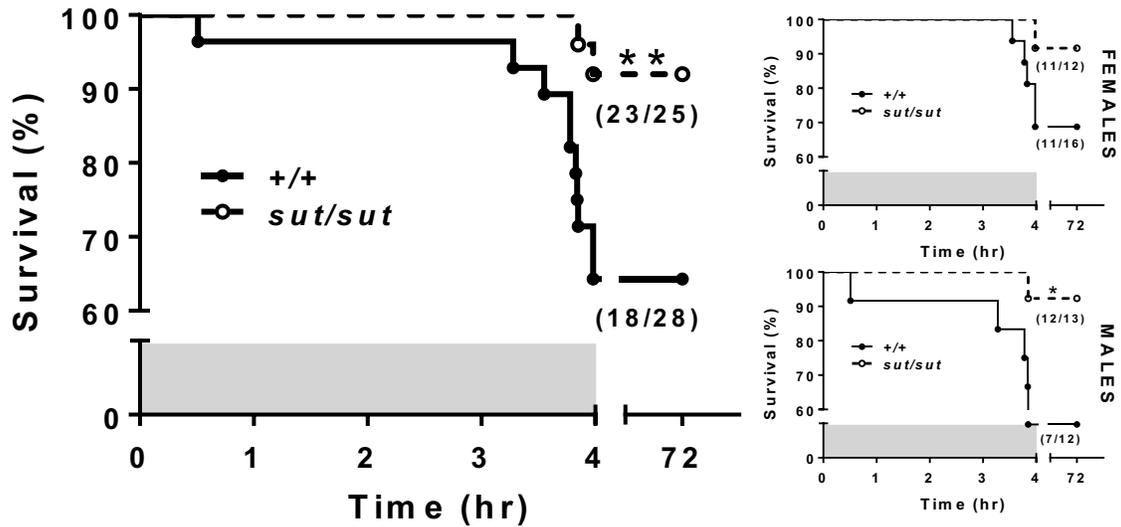

***KA-induced hippocampal neural degeneration occurs in different sub-regions in *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> mice.***

A subset of *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> mice dosed with 22.5 mg/kg KA (Fig. 4.3A) were sacrificed 72 hr post-seizure initiation and brains were processed for thionin or Fluoro-Jade C staining. All of the tissue analyzed was derived from *SLC7A11*<sup>+/+</sup> (Fig. 4.7A, 5 females, 3 males) or *SLC7A11*<sup>sut/sut</sup> (Fig. 4.7B, 4 females, 1 male) mice that achieved behavioral seizure scores of 6 (generalized convulsion) or 7 (generalized convulsion with loss of righting reflex and/or violent jumping) over the course of the dosing paradigm. Despite their behavioral seizure similarities, the hippocampal neural degeneration in *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> mice occurred with striking sub-region specificity. Though the incidence of neural degeneration occurred in a similar fraction of *SLC7A11*<sup>+/+</sup> [37.5% (3/8; 2 males, 1 female)] and *SLC7A11*<sup>sut/sut</sup> [60% (3/5; 1 male, 2 females)] mice ( $p = 0.5921$ ; Fisher's exact test), degeneration in the *SLC7A11*<sup>+/+</sup> mice

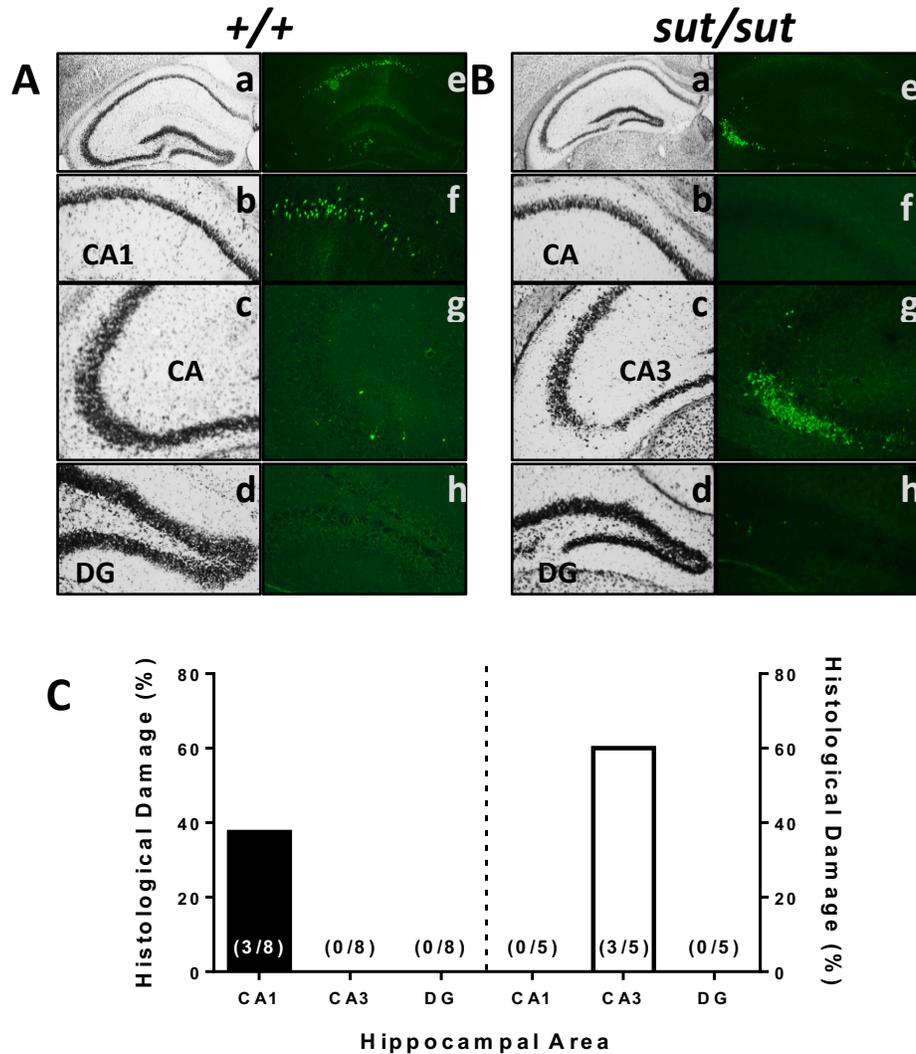

**Figure 4.5 Effect of SLC7A11 disruption on incidence of status epilepticus SE in the escalating KA paradigm.**

**A-C)** Bars represent the proportion (fraction within bars) of *SLC7A11*<sup>+/+</sup> [+/+, n = 27 (11M, 16F)] and *SLC7A11*<sup>sut/sut</sup> [*sut/sut*, n = 25, (13M, 12F)] mice that experienced a seizure score = 8 (SE) in the final 60 min quartile of the four hour KA dosing paradigm. \*Indicates significant between group difference (\**p* = 0.0189, \*\**p* = 0.0013, \*\*\**p* < 0.0001; Fisher's exact test).

**Figure 4.6 Effect of SLC7A11 disruption on mortality in the escalating KA paradigm.**

**A-C)** Kaplan-Meier survival curves up to 72 hr following initial KA dose for *SLC7A11*<sup>+/+</sup> [+/+, n = 28 (12M, 16F)] and *SLC7A11*<sup>*sut/sut*</sup> [*sut/sut*, n = 25, (13M, 12F)] (A) females and males combined, (B) females, or (C) males are graphed. Each data point represents the time at which individual mice died during the KA dosing protocol or over the following 72 hr. Fractions represent the proportion of mice that survived the 240 min KA paradigm (shaded region). \*Indicates significant between group difference (\**p* = 0.0402, \*\**p* = 0.0137; Mantel-Cox log-rank test).

**Figure 4.7 Comparison of cellular degeneration in hippocampus of  $SLC7A11^{+/+}$  and  $SLC7A11^{sut/sut}$  mice exposed to the escalating KA dose paradigm**

A cohort of  $SLC7A11^{+/+}$  and  $SLC7A11^{sut/sut}$  mice responding to the escalated KA dosing paradigm with a seizure score  $\geq 6$  were sacrificed 72 hr later by transcardial perfusion and fixation with 4% PFA. Brains were removed and coronal sections of 14  $\mu$ m thickness were taken at 28  $\mu$ m intervals spanning the hippocampal formation.

**A-B)** Representative photomicrographs of (A)  $SLC7A11^{+/+}$  ( $+/+$ ,  $n = 8$ ) and (B)  $SLC7A11^{sut/sut}$  ( $sut/sut$ ,  $n = 5$ ) brain sections stained with (a-d) thionin or (e-h) Fluoro-Jade C. Photomicrographs represent the hippocampal formation  $\approx -1.2$  to  $-1.9$  anterior to posterior from bregma (a, e; 4X); the CA1 (b, f; 10X); the CA3 (c, g; 10X); and the dentate gyrus (DG) (d, h; 10X).

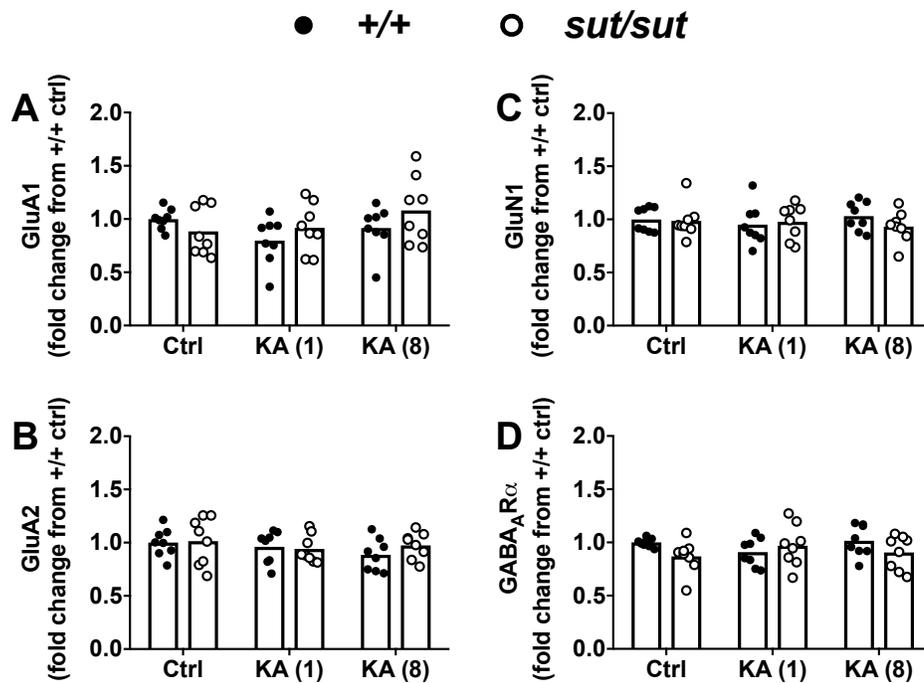

**C) Incidence of hippocampal histological damage:** Bars represent the proportion (fraction within bars) of  $SLC7A11^{+/+}$  ( $+/+$ , black bar) and  $SLC7A11^{sut/sut}$  ( $sut/sut$ , blue bar) mice with degenerating cells in the hippocampal formation sub-regions (CA1, CA3, or DG) as indicated by positive Fluoro-Jade C staining.

occurred primarily in the hippocampal CA1 sub-region whereas degeneration was limited to area CA3 in *SLC7A11<sup>sut/sut</sup>* mice (Fig. 4.7C). This was demonstrated by pyknosis or green fluorescence predominating in the CA1 (Fig. 4.7Ab and Fig. 4.7Af) or CA3 (Fig. 4.7Bc and Fig. 4.7Bg) of *SLC7A11<sup>+/+</sup>* or *SLC7A11<sup>sut/sut</sup>* mice, respectively.

### ***Plasma membrane protein expression levels***

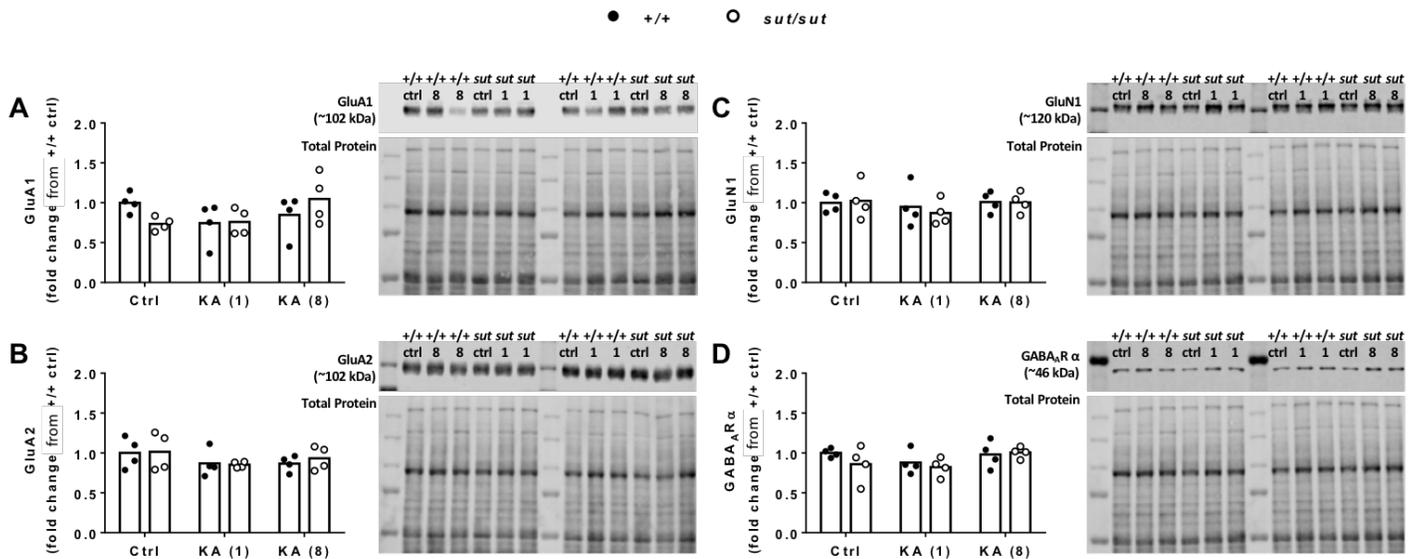

Despite receiving 22.5 mg/kg KA over the course of the escalating dosing paradigm, the majority of *SLC7A11<sup>sut/sut</sup>* mice exhibited profound hypo-excitability (seizure score = 1) in the fourth quartile of the protocol, a behavioral state polar opposite to *SLC7A11<sup>+/+</sup>* littermate controls who entered into behavioral status epilepticus (seizure score = 8). Given that aberrations in plasma membrane levels of AMPA (GluA1, GluA2), NMDA (GluN1), or GABA (GABA<sub>A</sub>R $\alpha$ ) receptor subunits are associated with abnormal neuronal synchronization (Kelley et al 2016, Mathern et al 1998, Raol et al 2006), we measured cortical plasma membrane expression levels of this suite of proteins to investigate whether alterations in such could underlie the behavioral hypo-excitability observed in the majority of *SLC7A11<sup>sut/sut</sup>* mice.

As such, comparisons were made between cortical plasma membrane proteins derived from naïve *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* mice as well as mice of each genotype that entered into a state of KA-induced hypomobility (MMSS = 1) or status epilepticus (MMSS = 8) in the final quartile of the escalating dose paradigm. Western blot analysis revealed no change in female and male *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* GluA1 (Fig. 4.8A), GluA2 (Fig. 4.8B), GluN1 (Fig. 4.8C), or GABA<sub>A</sub>R $\alpha$  (Fig. 4.8D) expression levels (two-way ANOVA with Tukey's multiple comparisons). Moreover,

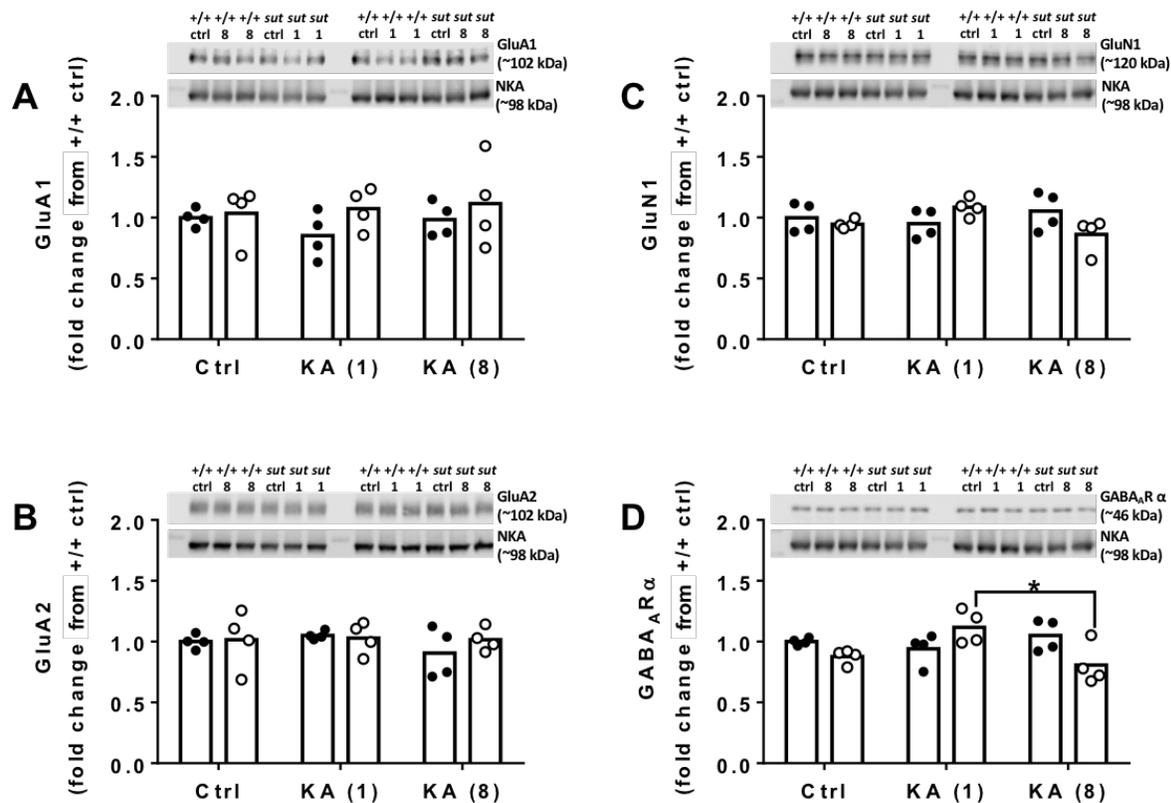

**Figure 4.8 Comparison of plasma membrane protein expression in  $SLC7A11^{+/+}$  and  $SLC7A11^{sut/sut}$  mice**

Plasma membrane protein levels in cortex derived from female and male  $SLC7A11^{+/+}$  ( $+/+$ ) or  $SLC7A11^{sut/sut}$  ( $sut/sut$ ) littermates naïve to any treatment (ctrl) or mice exhibiting hypo-mobility [KA (1)] or status epilepticus [KA (8)] in the final quartile of the four hour escalating dose paradigm were compared using Western blot analysis (see methods). Each data point [closed black circles ( $+/+$ ;  $n = 8$ ) or open circles ( $sut/sut$ ;  $n = 8$ )] represents the level of cortical (A) GluA1, (B) GluA2, (C) GluN1, or (D) GABA<sub>A</sub>R $\alpha$  protein following normalization to their respective loading control (i.e., Na<sup>+</sup>/K<sup>+</sup> ATPase levels or total protein) and subsequent normalization to  $+/+$  controls. Bars indicate the mean fold change from control ( $+/+$ ), which was set to one. Cortical plasma membrane protein expression levels were compared using a two-way ANOVA on log-transformed data.

**Figure 4.9 Comparison of plasma membrane protein expression in female *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> mice**

Plasma membrane protein levels in cortex derived from female *SLC7A11*<sup>+/+</sup> (+/+) or *SLC7A11*<sup>sut/sut</sup> (*sut/sut*) littermates naïve to any treatment (ctrl) or mice exhibiting hypomobility [KA (1)] or status epilepticus [KA (8)] in the final quartile of the four hour escalating dose paradigm were compared using Western blot analysis (see methods). Each data point [closed black circles (+/+; n = 4) or open circles (*sut/sut*; n = 4)] represents the level of cortical (A) GluA1, (B) GluA2, (C) GluN1, or (D) GABA<sub>A</sub>R $\alpha$  protein following normalization to their respective loading control (i.e. total protein levels) and subsequent normalization to +/+ controls. Bars indicate the mean fold change from control (+/+), which was set to one. Representative Western blots of +/+ and *sut/sut* cortical plasma membrane proteins are shown beside their respective graphs. Cortical plasma membrane protein expression levels were compared using a two-way ANOVA on log-transformed data.

**Figure 4.10 Comparison of plasma membrane protein expression in male *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> mice**

Plasma membrane protein levels in cortex derived from male *SLC7A11*<sup>+/+</sup> (+/+) or *SLC7A11*<sup>sut/sut</sup> (*sut/sut*) littermates naïve to any treatment (ctrl) or mice exhibiting hypomobility [KA (1)] or status epilepticus [KA (8)] in the final quartile of the four hour escalating dose paradigm were compared using Western blot analysis (see methods). Each data point [closed black circles (+/+; n = 4) or open circles (*sut/sut*; n = 4)] represents the level of cortical (A) GluA1, (B) GluA2, (C) GluN1, or (D) GABA<sub>A</sub>R $\alpha$  protein following normalization to their respective loading control (i.e., Na<sup>+</sup>/K<sup>+</sup> ATPase [NKA] levels) and subsequent normalization to +/+ controls. Bars indicate the mean fold change from control (+/+), which was set to one. Representative Western blots of +/+ and *sut/sut* cortical plasma membrane proteins are shown above their respective graphs. Cortical plasma membrane protein expression levels were compared using a two-way ANOVA on log-transformed data. An asterisk (\*) represents a significant between group difference ( $p < 0.05$ ).

stratification of this data by sex revealed a similar trend in female *SLC7A11<sup>+/+</sup>* as compared to *SLC7A11<sup>sut/sut</sup>* sex-matched littermates, who also demonstrated similar levels of GluA1, GluA2, GluN1, and GABA<sub>A</sub>R $\alpha$  protein levels (Fig. 4.9; two-way ANOVA with Tukey's multiple comparisons). Interestingly, while glutamate receptor subunits were similar between male *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* sex-matched littermates regardless of treatment (Fig. 4.10A-C), male *SLC7A11<sup>sut/sut</sup>* mice that became hypomobile by the end of the four-hour protocol demonstrated elevated GABA<sub>A</sub>R $\alpha$  expression levels as compared to male *SLC7A11<sup>sut/sut</sup>* mice that entered into status epilepticus (Fig. 4.10D,  $p < 0.05$ , two-way ANOVA with Tukey's multiple comparisons).

#### 4.5 Discussion

Results presented in Chapter 2 demonstrated that *SLC7A11<sup>sut/sut</sup>* mice have a decreased seizure threshold upon administration of an acute dose of PTZ. Despite this, *SLC7A11<sup>sut/sut</sup>* mice were less susceptible to PTZ-kindling (Chapter 3), suggesting that  $Sx_C^-$  contributes to E/I balance in a context-dependent manner. The present chapter extends these findings by demonstrating that alterations in excitability observed in *SLC7A11<sup>sut/sut</sup>* mice were generalizable to acute and elevated KA dosing seizure paradigms.

KA induces excitatory activity by binding to both AMPA receptors as well as its own cognate receptors (Vincent & Mulle 2009). In response to an acute systemic dose of KA, a significantly greater number of female and male *SLC7A11<sup>sut/sut</sup>* mice experienced a clonic or convulsive seizure as compared to *SLC7A11<sup>+/+</sup>* littermates, indicating that they have a decreased KA-induced seizure threshold. While these results support our initial studies using the GABA<sub>A</sub>R antagonist PTZ (Chapter 2), they are in

contrast with results reported by De Bundel et al demonstrating that transgenic xCT null (xCT<sup>-/-</sup>) mice on a C57BL/6 background require a significantly greater dose of KA to elicit behavioral clonus, and thus have an increased seizure threshold, as compared to xCT<sup>+/+</sup> littermate controls (De Bundel et al 2011). Given that both the xCT<sup>-/-</sup> and *SLC7A11<sup>sut/sut</sup>* mice are xCT null (Chintala et al 2005, De Bundel et al 2011, McCullagh & Featherstone 2014), the reason for the discrepancy in findings is not immediately clear. However, it may be accounted for by differences in experimental paradigms. In De Bundel et al, continuous intravenous infusion of chemoconvulsant resulted in rapid behavioral seizure onset such that clonic seizures were evoked in xCT<sup>+/+</sup> and xCT<sup>-/-</sup> mice by the time 58.1 or 75.6 mg/kg KA was infused, respectively (De Bundel et al 2011). However, it is difficult to attribute behavioral activity to a given dose when the dose is continuously changing, and it is possible that 58 mg/kg KA could elicit clonus in both xCT<sup>+/+</sup> and xCT<sup>-/-</sup> mice, but xCT<sup>-/-</sup> mice have an increase in clonic seizure latency. While the clonic latencies were not calculated in De Bundel et al, keeping the weight of an animal constant, the rapid infusion rate (150 µl/min) utilized in this protocol would result in a dose of 58.1 mg/kg by ≈77 sec versus a dose of 75.6 mg/kg by ≈100 seconds, which were the doses that evoked clonic seizures in xCT<sup>+/+</sup> or xCT<sup>-/-</sup> mice, respectively. Whether this change represents a significant difference in latency to clonus (77 versus 100 sec) is uncertain. Despite the discrepancy between the De Bundel et al study and our own, the present findings in this chapter parallel the results seen using the GABA<sub>A</sub>R antagonist PTZ (Chapter 2), and provide further evidence that *SLC7A11<sup>sut/sut</sup>* mice have a decreased acute seizure threshold.

Interestingly, repeated administration of KA in the elevated dosing paradigm revealed the opposite behavioral results; regardless of sex, the majority of *SLC7A11<sup>sut/sut</sup>* mice became profoundly hypomobile as compared to *SLC7A11<sup>+/+</sup>* littermate controls in the final quartile of the dosing protocol. Given the acute hyper-excitability observed in the *SLC7A11<sup>sut/sut</sup>* mice, it is tempting to speculate that the hypomobility seen in the latter portion of the escalating dose paradigm is simply due to excessive excitation and a resultant comatose post-ictal state. However, this does not appear to be the case, as this type of hypo-activity is usually associated with death and the *SLC7A11<sup>sut/sut</sup>* mice exhibiting hypomobility in the final quartile fully recover – with diazepam administration ostensibly superfluous in some mice (S. Sears personal observations). In fact, *SLC7A11<sup>sut/sut</sup>* mice have significantly decreased mortality overall as compared to *SLC7A11<sup>+/+</sup>* littermate controls in this paradigm.

In the final quartile of the elevated dosing paradigm, *SLC7A11<sup>sut/sut</sup>* mice exhibited a significantly decreased incidence of status epilepticus as compared to *SLC7A11<sup>+/+</sup>* mice. KA-induced behavioral convulsions are typically associated with structural alterations, as excessive depolarization can result in cell death (Olney et al 1974), and cell populations in the CA3 sub-region of the hippocampal formation have been demonstrated to be particularly vulnerable to KA-induced degeneration (Nadler et al 1980). However, mouse strain differences with respect to KA-induced degeneration do exist (Schauwecker 2003). As such, a subset of mice that attained a seizure score  $\geq 6$  were examined for overt hippocampal cellular degeneration. Interestingly, degeneration was not pervasive in every mouse examined, though of the mice that did exhibit cell loss, the hippocampal sub-region affected was strikingly genotype specific

with the CA1 and CA3 region exhibiting neural degeneration in *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* mice, respectively. Although xCT is expressed throughout the hippocampal formation, Ottsted-Hansen and colleagues recently demonstrated that xCT protein levels are greatest in the *stratum lacunosum moleculare* (SLM) and the molecular layer of the dentate gyrus (DG) (Ottstad-Hansen et al 2018). Interestingly, afferent projections from the entorhinal cortex (EC) terminate in both of these layers (Amaral et al 2007). This gives rise to the intriguing possibility that afferent EC projections to the SLM, together with  $Sx_c^-$  signaling, promotes neural degeneration in the CA1 hippocampal sub-region, and that lack of  $Sx_c^-$  thwarts this degeneration. Although the DG molecular layer is relatively cell-free – containing granule cell dendrites and inhibitory basket cells (Amaral et al 2007) – it is possible that afferent EC projections, together with  $Sx_c^-$  signaling, promotes basket cell-mediated inhibitory drive onto granule cells, thus thwarting over-activation of their CA3 synaptic targets and preventing KA-mediated CA3 cell death. Conversely, lack of  $Sx_c^-$  signaling in the molecular layer of *SLC7A11<sup>sut/sut</sup>* mice could render DG granule cells hyper-active, thus underlying the enhanced neural degeneration of their CA3 synaptic partners. Regardless of the underlying mechanism, the sub-region specific differences in *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* mice neural degeneration elicited by an elevated dose of KA suggest that  $Sx_c^-$  signaling regulates hippocampal circuitry. Nevertheless, hippocampal sub-region notwithstanding, the incidence of KA-induced cellular degeneration was similar in either genotype. Taken together, although not completely comparable to the chronic 21-day PTZ-kindling paradigm (Chapter 3), the behavioral hypo-excitability observed in response to an elevated KA dosing protocol in the present

chapter is qualitatively similar, suggesting that loss of  $Sx_c^-$  increases seizure threshold in response to repeated/chronic chemoconvulsant administration.

The increased synaptic drive elicited by repeated chemoconvulsant administration could plausibly engage homeostatic synaptic scaling mechanisms to allow stabilization of neuronal firing rate (Christie & Jahr 2008, Turrigiano 2008, Turrigiano et al 1998). This process is largely accomplished through the addition and subtraction, respectively, of ionotropic AMPA (O'Brien et al 1998, Turrigiano et al 1998, Wierenga et al 2005), NMDA (Mu et al 2003, Rao & Craig 1997, Watt et al 2000) or GABA<sub>A</sub> (Kilman et al 2002, Stellwagen et al 2005) receptors at the postsynaptic membrane. As such, we compared glutamate and GABA<sub>A</sub> receptor levels in cortical plasma membrane of naïve or KA-treated *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* mice. Out of all of the receptors investigated, the only difference observed was in GABA<sub>A</sub>R $\alpha$  levels: male, but not female, *SLC7A11<sup>sut/sut</sup>* mice that attained a MMSS = 1 (hypomobility) in the final quartile of the escalated dosing paradigm had increased GABA<sub>A</sub>R $\alpha$  levels as compared to sex-matched *SLC7A11<sup>sut/sut</sup>* mice that reached a MMSS = 8 (status epilepticus). However, neither KA-treated group significantly differed from naïve *SLC7A11<sup>sut/sut</sup>* mice nor from naïve or KA-treated *SLC7A11<sup>+/+</sup>* sex-matched controls. These results give rise to the intriguing possibility that KA-administration resulting in a slight increase in GABA<sub>A</sub>R $\alpha$  expression in the *SLC7A11<sup>sut/sut</sup>* mice confers diminished excitatory seizure activity – a behavioral state evident in the majority of *SLC7A11<sup>sut/sut</sup>* mice – whereas a slight decrease in GABA<sub>A</sub>R $\alpha$  expression does the opposite. However, these findings do not rule out the possibility that the changes detected in plasma membrane are driven by alterations in extrasynaptic (Brickley & Mody 2012) versus

synaptic GABA<sub>A</sub>Rs, and it will be important to determine whether GABA<sub>A</sub>R-dependent inhibitory postsynaptic currents (IPSCs) are functionally enhanced in the KA-treated male *SLC7A11<sup>sut/sut</sup>* mice with a fourth quartile MMSS = 1. Nevertheless, it is plausible that the fourth quartile hypo-excitability observed in *SLC7A11<sup>sut/sut</sup>* male mice is driven by an increase in plasma membrane GABA<sub>A</sub>R $\alpha$  expression. The mechanism conferring behavioral hypo-excitability in female *SLC7A11<sup>sut/sut</sup>* mice requires further investigation. Finally, the idea that this phenotype (behavioral hypo-excitability) is sex-independent yet could be driven by sex-dependent differences (altered GABA<sub>A</sub>R expression in males versus unknown mechanism(s) in females) is perhaps unsurprising given results described in Chapter 2 of this dissertation, whereby a sex-independent hyperexcitable phenotype occurred in association with sex-dependent cellular morphological changes.

Taken together, our results demonstrate that *SLC7A11<sup>sut/sut</sup>* mice have a decreased convulsive seizure threshold in response to acute KA administration whereas an elevated dosing paradigm using the same chemoconvulsant results in *SLC7A11<sup>sut/sut</sup>* behavioral hypoactivity as compared to *SLC7A1<sup>+/+</sup>* littermate controls. These results suggest that Sx<sub>c</sub><sup>-</sup> contributes to E/I balance in a context-dependent manner. Moreover, KA-induced behavioral hypo-excitability in male *SLC7A11<sup>sut/sut</sup>* mice occurs in association with increased GABA<sub>A</sub>R $\alpha$  levels, suggesting that a change in GABAergic function could underlie this phenotype. Whether this alteration in GABA<sub>A</sub>R $\alpha$  protein levels confer a functional change in males, and the exact mechanism by which loss of Sx<sub>c</sub><sup>-</sup> signaling confers fourth quarter behavioral hypo-excitability in female mice, requires further experimentation.

## **Chapter 5: Discussion, conclusions, and future directions**

## 5.1 Main findings

The goal of this dissertation was to elucidate whether and how System  $x_c^-$  ( $Sx_c^-$ ) signaling contributes to the excitatory/inhibitory (E/I) balance in brain. The main findings of this dissertation are that (1) loss of  $Sx_c^-$  in *SLC7A11<sup>sut/sut</sup>* mice renders them hyper-excitable in response to acute administration of two pharmacologically distinct chemoconvulsants, PTZ or KA. Furthermore, baseline hyper-excitability in *SLC7A11<sup>sut/sut</sup>* mice occurs in association with morphological alterations at the gross, cellular, and sub-cellular level, as well as with alterations in plasma membrane glutamate receptor subunit expression and brain redox status, any or all of which could underlie the behavioral responses elucidated. (2) Despite acute hyper-excitability in response to either PTZ or KA, chronic/repeated dosing with these same chemoconvulsants elicits a polar opposite response – behavioral hypo-excitability – in *SLC7A11<sup>sut/sut</sup>* mice as compared to *SLC7A11<sup>+/+</sup>* littermate controls.

## 5.2 Acute hyper-excitability in $Sx_c^-$ null mice occurs in association with morphological, redox, and plasma membrane protein alterations

Findings presented in this dissertation demonstrate a sex-independent hyper-excitability phenotype uncovered in *SLC7A11<sup>sut/sut</sup>* mice via administration of two pharmacologically distinct chemoconvulsants, PTZ or KA. *SLC7A11<sup>sut/sut</sup>* mice are viable, fertile, do not display spontaneous seizure activity, and, other than a subtle grey coat color, particularly apparent in juvenile mice three to four weeks of age, are indistinguishable from their C3H/HeSnJ *SLC7A11<sup>+/+</sup>* littermates [personal observations and (Chintala et al 2005, Lane 1988)]. Despite their overt similarities to *SLC7A11<sup>+/+</sup>*

controls, the behavioral hyper-excitability in *SLC7A11<sup>sut/sut</sup>* mice upon acute chemoconvulsant administration is indicative of a brain E/I imbalance.

Previous characterization of male xCT transgenic null mice on a C57BL/6 background revealed increased spontaneous and evoked miniature excitatory postsynaptic currents (mEPSCs) and synaptic AMPA receptor expression levels in hippocampal CA1 (Williams & Featherstone 2014). These findings, if true in the *SLC7A11<sup>sut/sut</sup>* mice, could explain the increased susceptibility to chemoconvulsant-induced acute seizure activity (Croll et al 1999, Greenwood et al 2009). However, neither male (Chapter 3, Fig. 3.6) nor female (Supplementary Fig. S4) *SLC7A11<sup>sut/sut</sup>* mice have increased levels of plasma membrane glutamate receptors. In fact, the AMPA receptor subunit GluA1 is *decreased* in cortical plasma membrane of male (Chapter 3, Fig. 3.6) and hippocampal plasma membrane of female (Supplementary Fig. S4) *SLC7A11<sup>sut/sut</sup>* mice as compared to *SLC7A11<sup>+/+</sup>* sex-matched littermate controls. However, our plasma membrane measurements capture receptors of both synaptic and extrasynaptic origin, as well as receptors in all hippocampal and cortical sub-regions. Thus, in order to determine if post-synaptic membranes are strengthened in *SLC7A11<sup>sut/sut</sup>* mice, dendritic spine head width – which correlates with glutamate receptor abundance – was measured in cortical layer V pyramidal cells. In agreement with findings demonstrating increased synaptic strength in male xCT transgenic null mice (Williams & Featherstone 2014), spine head widths in male *SLC7A11<sup>sut/sut</sup>* mice are increased as compared to *SLC7A11<sup>+/+</sup>* sex-matched littermate controls (Chapter 2, Fig. 2.7). Thus, despite a reduction in total cortical plasma membrane GluA1 levels in *SLC7A11<sup>sut/sut</sup>* male mice, synaptic strength – as measured by spine head width – was

enhanced, which could plausibly underlie the acute hyper-excitability in *SLC7A11<sup>sut/sut</sup>* males. Surprisingly, results in female mice demonstrated the opposite: spine head widths of *SLC7A11<sup>sut/sut</sup>* mice were significantly decreased as compared to *SLC7A11<sup>+/+</sup>* sex-matched littermate controls (Chapter 2, Fig. 2.7). However, these findings do not rule out the possibility of changes to hippocampal synapses, which, unfortunately, were precluded from our analysis due to the complexity and density of Golgi-Cox stained neurons in the hippocampal formation. To further understand how these morphological changes translate functionally – and to explore hippocampal synapses – an instructive next step would be to record (miniature) excitatory postsynaptic potentials [(m)EPSPs] from whole-cell patch-clamped neurons in order to precisely and quantitatively detect changes in quantal content and/or postsynaptic glutamate receptors that could underlie a shift in E/I balance towards excitation.

To explore further mechanisms underlying hyper-excitability in *SLC7A11<sup>sut/sut</sup>* mice, two additional lines of inquiry, cellular morphology and redox balance, were investigated in this dissertation. With respect to morphology, the work presented herein uncovered that (1) sex-differences in cellular morphology exist in *SLC7A11<sup>+/+</sup>* mice on the C3H/HeSnJ background and (2) within-sex morphological alterations were uncovered that could plausibly contribute to genotype-dependent differences in E/I balance. With regards to the first finding, our results indicate that soma size is significantly increased in female *SLC7A11<sup>+/+</sup>* as compared to male *SLC7A11<sup>+/+</sup>* mice on the C3H/HeSnJ background (Chapter 2, Fig. 2.5). To our knowledge, this is the first account of sex-differences in cortical layer V neuronal soma size reported in mouse. Functionally, it is unclear why a sex-difference in soma size exists. However, loss of

$Sx_c^-$  lends credibility to one possibility: sex morphological differences exist to prevent functional differences (De Vries 2004). This idea seems plausible given that loss of  $Sx_c^-$  in female *SLC7A11<sup>sut/sut</sup>* mice leads to a reduction in soma area – which itself is associated with decreased inhibition (Hsu et al 2012, Ye et al 2015) – and occurs in association with increased behavioral excitability (decreased acute seizure threshold). As such, an increase in soma area in *SLC7A11<sup>+/+</sup>* females as compared to *SLC7A11<sup>+/+</sup>* males may be important in maintaining an elevated acute seizure threshold in female *SLC7A11<sup>+/+</sup>* mice. Of note, a slight decrease in *SLC7A11<sup>+/+</sup>* male versus female acute seizure threshold was uncovered in Chapter 2 (Fig. 2.10), and as such, male mice required a lower acute PTZ (or KA) dose to uncover an E/I imbalance in *SLC7A11<sup>sut/sut</sup>* mice. Whether or not soma size is integrally linked to maintenance of E/I balance in females requires further investigation, including characterizing the abundance and strength of perisomatic inhibitory synapses using immunohistochemistry and electrophysiology, respectively.

If soma size correlates with E/I balance in female *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* mice, does the same hold true for males? Our results indicate that soma size is similar in male *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* sex-matched littermate controls. However, our results demonstrate that dendritic complexity is significantly decreased in *SLC7A11<sup>+/+</sup>* male as compared to female mice on the C3H/HeSnJ background (Chapter 2, Fig. 2.3). Once again, to our knowledge, this is the first report of sex-differences in cortical layer V dendritic complexity in mouse. Furthermore, loss of  $Sx_c^-$  in male mice increases dendritic complexity as compared to *SLC7A11<sup>+/+</sup>* sex-matched littermates, such that their complexity is indistinguishable from female mice (Chapter 2, Fig. 2.3). Thus –

similar to soma size – these findings raise the intriguing possibility that morphological sex-differences in dendritic complexity exist to maintain functional E/I balance. Given that enhanced dendritic complexity is associated with increased excitability (Klenowski et al 2016, Mainen & Sejnowski 1996), it is tempting to speculate that an increase in cortical dendritic complexity underlies the decreased seizure threshold in *SLC7A11<sup>sut/sut</sup>* male mice. Whether this morphological change is associated with enhanced neuronal excitability, such as increases in EPSC frequency or repetitive spikes, will require electrophysiological confirmation.

Given that  $Sx_c$ -mediated cystine import provides cells with the rate-limiting substrate (cysteine) for synthesis of the thiol antioxidant GSH, we also explored whether alterations in levels of reduced and oxidized glutathione (GSH and GSSG) or cysteine (cysteine and cystine) could account for an E/I imbalance in *SLC7A11<sup>sut/sut</sup>* mice. Interestingly, the brains of *SLC7A11<sup>sut/sut</sup>* females (Supplementary Fig. S2), but not males (Chapter 3, Fig. 3.5), are under oxidative stress as demonstrated by elevated cortical GSSG and hippocampal cystine levels compared to sex-matched *SLC7A11<sup>+/+</sup>* littermate controls. Given that increased levels of oxidants can decrease seizure threshold (Liang & Patel 2004), the cysteine prodrug N-acetylcysteine (NAC) was administered to female *SLC7A11<sup>sut/sut</sup>* mice and seizure threshold determined (Supplementary Fig. S3). Our results indicate that NAC administration over eight days does not increase *SLC7A11<sup>sut/sut</sup>* seizure threshold as compared to vehicle-administered *SLC7A11<sup>sut/sut</sup>* littermate controls, suggesting that the decreased acute seizure threshold in female *SLC7A11<sup>sut/sut</sup>* mice is not due to a redox imbalance. A potential caveat to this study includes the length of NAC administration, which may not have been extensive

enough to restore brain redox status. However, oral supplementation of NAC for seven days at the same dose used by our laboratory has been demonstrated to elevate brain thiol content in the excitatory amino acid transporter 3 (EAAC1) null mouse (Berman et al 2011). Conversely, in the case of the *SLC7A11<sup>sut/sut</sup>* mice, a balanced redox status may be required *throughout* development in order to properly establish E/I balance, especially if redox state influences other downstream effectors that ultimately confer E/I balance. One plausible example of redox status affecting E/I balance indirectly is through soma size: during periods of decreased protein synthesis, net loss of cellular protein results in somatic atrophy (Franklin & Johnson 1998). Interestingly, under periods of oxidative stress, shunting of cysteine from its role as a macromolecular building block to its incorporation into antioxidants, including GSH, is upregulated in order to confer cellular protection (Ratan et al 1994). As such, it is conceivable that a redox imbalance in female *SLC7A11<sup>sut/sut</sup>* mice facilitates cysteine shunting from protein synthesis to GSH synthesis, resulting in a reduction in soma size – and an associated decrease in inhibitory tone – and ultimately leading to a decrease in seizure threshold. A logical future direction is to administer NAC to female *SLC7A11<sup>sut/sut</sup>* mice throughout development, including *in utero* via dietary supplementation to the dam, to determine if this rescues cell body size and/or seizure threshold to that of *SLC7A11<sup>+/+</sup>* sex-matched littermate controls.

### **5.3 Delayed hypo-excitability in $Sx_c^-$ null mice**

Despite hyper-excitability elicited in response to an acute dose of chemoconvulsant, *SLC7A11<sup>sut/sut</sup>* mice show behavioral signs of hypoexcitability upon

chronic administration of PTZ (Chapter 3, Fig. 3.1) or repeated administration of KA (Chapter 4, Fig. 4.3). Specifically, repeated daily injections of an initially sub-convulsant dose of PTZ ultimately leads to a permanent decrease in the threshold of excitability in *SLC7A11<sup>+/+</sup>* mice (i.e., mice become kindled), whereas the percent *SLC7A11<sup>sut/sut</sup>* mice that kindle over the same 21 days is significantly lower (Chapter 3, Fig. 3.1). Similarly, *SLC7A11<sup>+/+</sup>* mice attain status epilepticus (seizure score = 8) after repeated dosing with KA, whereas *SLC7A11<sup>sut/sut</sup>* mice become hypomobile (seizure score = 1) (Chapter 4, Fig. 4.3). These data suggest that  $Sx_c^-$  activity modulates synaptic strength *in vivo* in a context-dependent manner.

In Chapter 3, PTZ-kindling was explored in male mice only, as the low seizure-threshold in *SLC7A11<sup>sut/sut</sup>* females precluded our ability to carry out a kindling protocol (data not shown). Post-kindling, our results indicate that mossy fiber sprouting and cellular degeneration are unlikely to contribute to the decreased incidence of PTZ-kindling in *SLC7A11<sup>sut/sut</sup>* mice, as neither reactive synaptogenesis nor cell loss were observed in mice of either genotype. Rather, it was postulated in Chapter 3 that decreased PTZ-kindling in *SLC7A11<sup>sut/sut</sup>* mice may be a result of hypo-glutamatergic signaling given that glutamate levels (McCullagh & Featherstone 2014) and basal plasma membrane expression levels of the glutamate receptor subunit GluA1 (Chapter 3, Fig. 3.6) are diminished in male *SLC7A11<sup>sut/sut</sup>* mice. However, morphological parameters presented in Chapter 2 indicate that, despite decreased plasma membrane GluA1 levels, cortical synapses may indeed be strengthened in male mice given their increased dendritic spine head widths (Chapter 2 Fig. 2.7). These contradictory results could be explained by the fact that plasma membrane protein expression levels are not

indicative of synaptic protein levels as they incorporate receptors expressed in both synaptic and extrasynaptic regions. As such, it will be necessary to perform *ex vivo* electrophysiological brain slice recordings to directly measure synaptic strength in *SLC7A11<sup>sut/sut</sup>* mice.

Chronic excitation elicited by PTZ-kindling (Kapur et al 1989a, Kapur et al 1989b, Schröder et al 1993) or status epilepticus (Friedman et al 1994, Goodkin et al 2005, Grooms et al 2000, Naylor et al 2013) is associated with alterations in neurotransmitter receptor mRNA or protein expression levels, with increases in glutamate receptor subunits GluN1 and GluA1 (Naylor et al 2013, Schröder et al 1993) or decreases in GluA2 (Grooms et al 2000) and GABAergic receptors (Goodkin et al 2005, Kapur et al 1989a, Kapur et al 1989b) demonstrated. In order to determine whether alterations in repeated/chronic chemoconvulsant administration provoked changes in receptor expression levels, we assessed levels of glutamate (GluA1, GluA2, and GluN1) and GABA (GABA<sub>A</sub>R $\alpha$ ) receptor subunits in plasma membrane following repeated KA administration, chosen because the paradigm is complete after 240 min and likely provides qualitatively the same data as the 21-day PTZ-kindling paradigm. While no changes in glutamate or GABA<sub>A</sub> receptor subunits between female or male *SLC7A11<sup>+/+</sup>* or *SLC7A11<sup>sut/sut</sup>* mice were detected, we did find that the behavioral response of male *SLC7A11<sup>sut/sut</sup>* mice within the final quartile of the dosing paradigm correlated with GABA<sub>A</sub>R $\alpha$  expression levels: *SLC7A11<sup>sut/sut</sup>* males that became hypomobile had significantly increased plasma membrane GABA<sub>A</sub>R $\alpha$  protein levels as compared to *SLC7A11<sup>sut/sut</sup>* males that entered into status epilepticus (Chapter 4, Fig. 4.10). Whether increases or decreases in GABA<sub>A</sub>R $\alpha$  expression underlies male *SLC7A11<sup>sut/sut</sup>*

behavioral hypomobility or status epilepticus, respectively, requires further experimentation. Moreover, this change was not detected in female *SLC7A11<sup>sut/sut</sup>* mice (Chapter 4, Fig. 4.9), and the mechanism underlying their behavioral hypo-excitability in the face of repeated KA administration remains unexplained.

The within-genotype change in GABA<sub>A</sub>R $\alpha$  expression in male *SLC7A11<sup>sut/sut</sup>* mice notwithstanding, receptor expression levels are overwhelmingly similar in *SLC7A11<sup>+/+</sup>* and *SLC7A11<sup>sut/sut</sup>* mice following the repeated KA dosing paradigm. However, just as with basal plasma membrane protein expression levels discussed earlier, a caveat to this study is plasma membrane measurements do not exclusively measure synaptic receptors. Thus, measuring synaptic activity via electrophysiology or measuring synaptic protein expression via immunohistochemistry will be important next step(s) in determining whether alterations in synaptic protein levels account for *SLC7A11<sup>sut/sut</sup>* behavioral hypo-excitability in the repeated/chronic chemoconvulsant dosing paradigms.

#### **5.4 Working model(s) to explain the dichotomy**

Synaptic scaling: Neurons detect fluctuations in extracellular glutamate levels and/or in synaptic drive and autonomously adjust the strength of their synapses up or down to stabilize firing via a process known as homeostatic synaptic scaling (Christie & Jahr 2008, Turrigiano 2008, Turrigiano et al 1998). This is largely accomplished through the addition and subtraction, respectively, of ionotropic AMPA receptors at the postsynaptic membrane (Turrigiano et al 1998, Wierenga et al 2005), although this can only occur within a modifiable range (Riout-Pedotti et al 2007, Riout-Pedotti et al

2000). For example, scaling-up of AMPA receptors to a “ceiling” results in an occlusion of processes dependent upon postsynaptic AMPA receptor membrane insertion, such as long-term potentiation (LTP) (Li et al 2016). Interestingly, hippocampal LTP is diminished in *SLC7A11<sup>sut/sut</sup>* mice and genetically engineered xCT nulls show deficits in hippocampal-dependent spatial learning – a process dependent upon postsynaptic AMPA receptor membrane insertion (De Bundel et al 2011, Li et al 2012). Moreover, both kindling-induced plasticity (Cain 1989, Goddard & Douglas 1975) and status epilepticus (Naylor et al 2013, Rice & DeLorenzo 1998, Rice et al 1998) share common mechanisms with LTP, including the insertion of postsynaptic glutamate receptors (Naylor et al 2013), a long-lasting increase in response to a constant stimulus (Cain 1989), and the dependency of this response on NMDAR activation (Rice & DeLorenzo 1998). Moreover, status epilepticus, and its subsequent epileptic sensitization, impaired performance of rats in the Morris water maze, suggesting that status epilepticus-induced neuronal sensitization and learning share common mechanisms (Rice et al 1998).

Given that enhanced expression of synaptic AMPA receptors has been demonstrated in the hippocampus of transgenic xCT null mice (Williams & Featherstone 2014), and that *SLC7A11<sup>sut/sut</sup>* males (but not females) have increased dendritic spine head widths as compared to *SLC7A11<sup>+/+</sup>* littermate controls (Chapter 2, Fig. 2.7), it is tempting to speculate that male mice null for *Sxc<sup>-</sup>* may have AMPA receptors scaled-up to the apex of their modifiable range. This endogenous “scaling-up” in male *SLC7A11<sup>sut/sut</sup>* mice, perhaps a result of diminished ambient extracellular glutamate levels (De Bundel et al 2011, Massie et al 2011b, McCullagh & Featherstone 2014),

could explain their decreased acute seizure threshold. Conversely, repeated/chronic chemoconvulsant administration in a system already at the “ceiling” of its modifiable range could cause homeostatic scaling-down of glutamate receptors, explaining the reduced excitability of *SLC7A11<sup>sut/sut</sup>* mice in the PTZ-kindling and repeated KA-dosing paradigm. Given that enhanced dendritic spine head width was observed in cortical neurons derived from male – but not female – *SLC7A11<sup>sut/sut</sup>* mice, if the aforementioned mechanisms are driving the dichotomous excitability in *SLC7A11<sup>sut/sut</sup>* mice, they may be sex-dependent and present exclusively in males. In line with this, decreased ambient glutamate levels – that could plausibly evoke an endogenous “scaling-up” of glutamate receptors – have been reported in male (De Bundel et al 2011, Massie et al 2011b, McCullagh & Featherstone 2014) but not female (Borra et al 2014) *Sx<sub>c</sub><sup>-</sup>* null mice. However, it should be noted that glutamate measurements were carried out in the striatum in *SLC7A11<sup>sut/sut</sup>* female mice (Borra et al 2014), and our dendritic spine head measurements were limited to the cortex (Chapter 2, Fig. 2.7). As such, it remains plausible that reduced glutamate levels or increased spine head width exist in other brain regions in female *Sx<sub>c</sub><sup>-</sup>* null mice, especially given that *Sx<sub>c</sub><sup>-</sup>* appears to contribute to ambient extracellular glutamate levels in a brain-region dependent manner (McCullagh & Featherstone 2014).

Redox balance: Alternatively, the dichotomous changes in excitability evoked by acute or repeated chemoconvulsant stimulus could be a result of a redox imbalance in *SLC7A11<sup>sut/sut</sup>* mice. Glutamate transporters and the NMDA receptor possess redox-sensing properties that regulate their activity (Aizenman et al 1989, Köhr et al 1994, Sullivan et al 1994, Trotti et al 1997). Moreover, manganese superoxide dismutase

(SOD2<sup>+/-</sup>) mice with chronic mitochondrial oxidative stress have a decreased KA-induced seizure threshold (Liang & Patel 2004). Given that female (but not male) *SLC7A11<sup>sut/sut</sup>* brains have elevated levels of oxidized GSH and cysteine, it is tempting to speculate that their reduced acute seizure threshold is a result of a redox imbalance.

Furthermore, LTP is diminished in GSH-deficient rodents (Almaguer-Melian et al 2000, Robillard et al 2011), and normalizing GSH levels can restore LTP (Robillard et al 2011). These findings stress the importance of redox balance in the regulation of synaptic plasticity. Given the mechanistic similarities between LTP and the sustained excitation elicited by chemoconvulsants *in vivo* (Cain 1989, Goddard & Douglas 1975, Naylor et al 2013, Rice & DeLorenzo 1998, Rice et al 1998), it is plausible that a redox imbalance could thwart the progression of PTZ-kindling or KA-induced status epilepticus in *SLC7A11<sup>sut/sut</sup>* mice, thus explaining their hypo-excitability in these models. As a redox imbalance was observed in female (Supplementary Fig. S2) – but not male (Chapter 3, Fig. 3.5) – *SLC7A11<sup>sut/sut</sup>* mice, if the aforementioned mechanisms are driving the dichotomous excitability in *SLC7A11<sup>sut/sut</sup>* mice, they may be sex-dependent and present exclusively in females.

## 5.5 Astrocytic maintenance of E/I balance

As discussed in Chapter 1, there is now indisputable evidence, stemming from both transcriptome and immunohistochemical analyses, that astrocytes are the primary cell types expressing Sx<sub>c</sub><sup>-</sup> in the mature brain *in vivo* (Ottestad-Hansen et al 2018, Pow 2001, Zhang et al 2014). As the most numerous glial subtype in the CNS, astrocytes perform a number of well-characterized homeostatic support functions, including

maintenance of perivascular homeostasis and blood brain barrier integrity (Alvarez et al 2013, Mathiisen et al 2010),  $K^+$  buffering (Orkand et al 1966), supplying neurons with energy substrates (Pellerin et al 1998) and neurotransmitter precursors (Bak et al 2006), and glutamate uptake via EAATs [reviewed in (Danbolt 2001)]. With respect to the latter, astrocytic EAAT1 or EAAT2 knock-out mice demonstrate prolonged seizure duration in an amygdala kindling model (Watanabe et al 1999) or spontaneous electroencephalographic seizures (Tanaka et al 1997), respectively, highlighting the potent ways in which astrocytes regulate synaptic transmission. Additionally, more recent evidence implicates astrocytes in the positive and negative regulation of CNS synaptogenesis through their release of soluble factors such as thrombospondins (TSPs)-1 and -2 (Christopherson et al 2005), Hevin and SPARC (Kucukdereli et al 2011), and glypicans 4 and 6 (Allen et al 2012). While the aforementioned functions render astrocytes capable of modulating synaptic transmission indirectly, astrocytes also play an active role at the synapse by both responding to (Ding et al 2013, Murphy-Royal et al 2015) and releasing (Allen et al 2012, Guthrie et al 1999, Malarkey & Parpura 2008, Schell et al 1995, Schmitt et al 2012) neurotransmitters. Moreover, astrocytes are capable of modulating both Hebbian and homeostatic synaptic plasticity through their release of the NMDA receptor co-agonist, D-serine (Henneberger et al 2010) and the cytokine TNF- $\alpha$  (Stellwagen & Malenka 2006), respectively.

In light of the multitude of ways in which astrocytes participate in CNS activity, the findings presented in this dissertation support a growing theme for astrocytic transporters – including  $Sx_c^-$  – in maintenance of E/I balance. Given that elevated KA dosing induced hippocampal neural degeneration in a sub-region dependent manner in

*SLC7A11<sup>sut/sut</sup>* and *SLC7A11<sup>+/+</sup>* littermate controls, our results also implicate  $Sx_c^-$  signaling in maintenance of hippocampal circuitry (Figure 4.7). Nevertheless, it is important to reiterate that the *SLC7A11<sup>sut/sut</sup>* mice used in this study harbor a global natural null mutation in the *SLC7A11* gene. Given that  $Sx_c^-$  is predominantly astrocytic it is tempting to speculate that the results herein are a result of astrocytic  $Sx_c^-$  signaling. However, the cell type specificity of the observations reported in this dissertation will be necessary to confirm using an astrocyte conditional *SLC7A11* null mouse.

## 5.6 Future directions

While the results presented in this dissertation demonstrate that  $Sx_c^-$  signaling regulates E/I balance in a context dependent manner, several future directions remain. Clearly, the dichotomy that was uncovered – that *SLC7A11<sup>sut/sut</sup>* mice are hyper-excitable or hypo-excitable depending on the chemoconvulsant dosing paradigm – is an interesting finding that warrants further investigation. Electrophysiological brain slice recordings from naïve mice, as well as from mice exposed to the repeated/chronic chemoconvulsant dosing paradigms described herein, should be made in order to understand physiological parameters – including both inhibitory and excitatory post-synaptic currents – driving neuronal activity that were potentially missed by our plasma membrane protein analysis. Electrophysiological slice recordings will also be informative to understand how the observed morphological alterations affect cell firing capacity. Furthermore, although our results indicate that NAC supplementation in female *SLC7A11<sup>sut/sut</sup>* mice – whose brains are under oxidative stress – does not increase their acute PTZ seizure threshold, a future direction includes supplementation with NAC

throughout their lives in order to thwart changes that might occur early in development that confer an E/I imbalance. Additionally, developmental NAC supplementation, as well as its continued supplementation throughout the repeated/chronic dosing paradigms, would be an interesting study to pursue in both females and males in order to determine if hypo-excitability observed therein is a result of oxidative stress. Finally, as mentioned above, in order to confirm the cell type specificity of the findings presented in this dissertation, it would be necessary to confirm our findings using an astrocyte conditional *SLC7A11* null mouse.

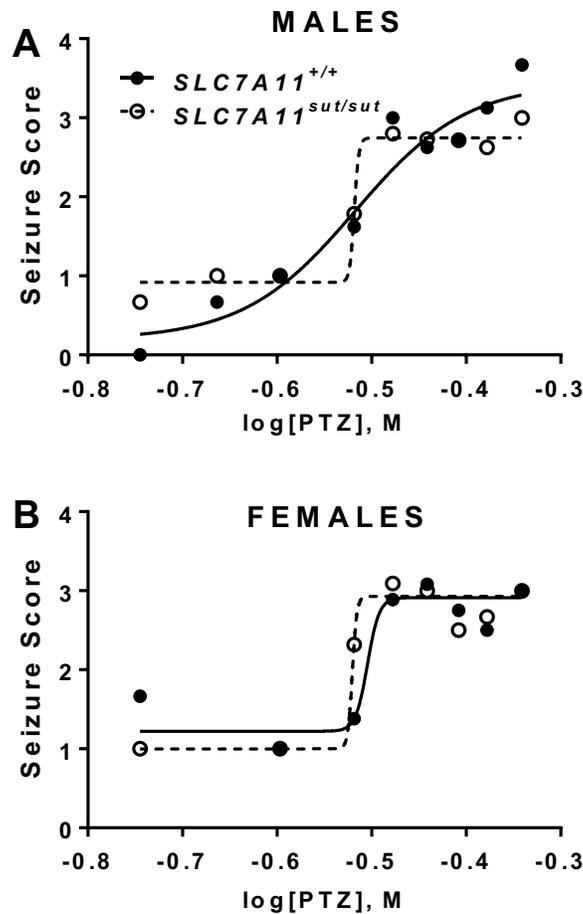

## 5.7 Significance

The purpose of this dissertation research was to investigate whether and how  $Sx_c^-$  signaling contributes to E/I balance *in vivo*. This line of inquiry was of interest given that an E/I imbalance is implicated in numerous neurological disorders (Gao & Penzes 2015, Nelson & Valakh 2015) and disease states (Foerster et al 2013, Fritschy 2008, Lai et al 2014, Ren et al 2018, Snyder et al 2005). The findings presented herein that loss of  $Sx_c^-$  thwarts the progression of excitability upon repeated/chronic chemoconvulsant application, including in a model of epileptogenesis, suggests that inhibition of  $Sx_c^-$  signaling may be a therapeutic option in individuals suffering from an E/I imbalance, such as those prone to develop epilepsy as a result of traumatic brain injury or glioblastoma. However, these results should be interpreted with caution given that loss of  $Sx_c^-$  also results in acute hyper-excitability. Thus, whether the acute hyper-excitability phenotype uncovered in *SLC7A11<sup>sut/sut</sup>* mice is a result of a developmental change or whether acute pharmacological inhibition of  $Sx_c^-$  elicits a similar acute hyper-

excitability needs to be determined prior to consideration of  $Sx_c^-$  targeting as a therapeutic option for individuals suffering an E/I imbalance.

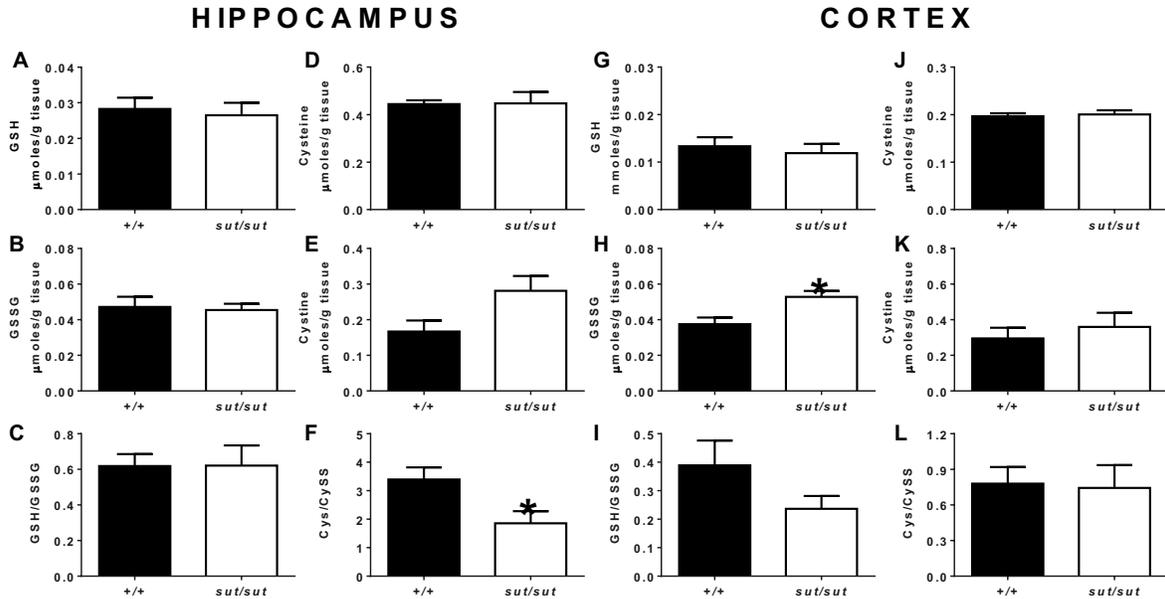

## Appendix

## Supplementary Figures

### Supplemental Figure S1: Acute PTZ dose response curve in female and male $SLC7A11^{+/+}$ and $SLC7A11^{sut/sut}$ mice

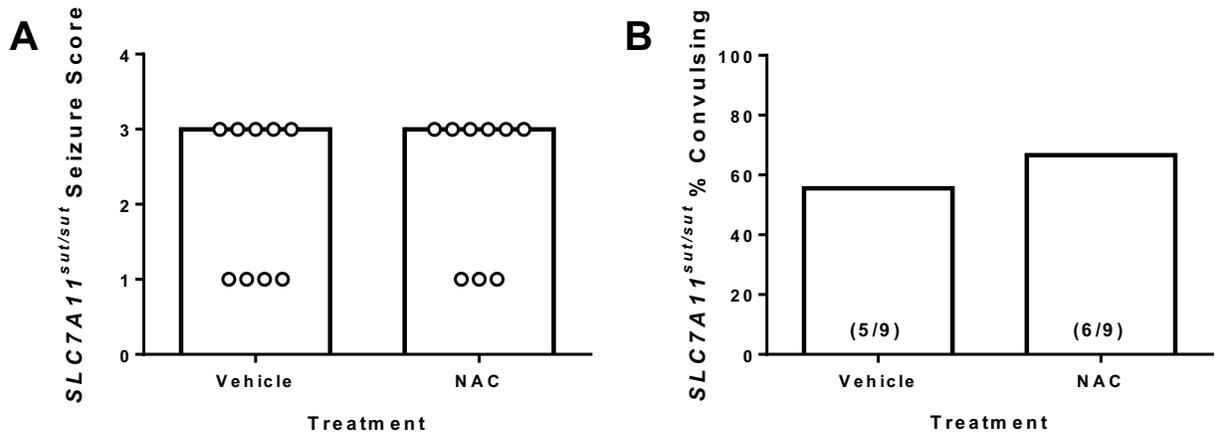

(A) Male  $SLC7A11^{+/+}$  ( $+/+$ ; n = 3-29) and  $SLC7A11^{sut/sut}$  ( $sut/sut$ ; n = 3-37) or (B) female  $SLC7A11^{+/+}$  ( $+/+$ ; n = 3-21) and  $SLC7A11^{sut/sut}$  ( $sut/sut$ ; n = 3-26) littermates were administered a single dose of PTZ (i.p.), after which behavior was monitored for 20-30 min. Seizure severity was scored using a 5-point scale as described in Chapter 2 materials and methods. Dose of PTZ (25-63 mg/kg) is expressed as log [PTZ], M. Symbols represent the mean maximal seizure score for  $+/+$  (closed black circles) and  $sut/sut$  (open circles) mice during the 30 min observation period.

**Supplemental Figure S2: Effect of SLC7A11 disruption on hippocampal and cortical reduced/oxidized glutathione and cysteine levels in female mice**

Naïve female *SLC7A11*<sup>+/+</sup> (+/+; n = 5) and *SLC7A11*<sup>sut/sut</sup> (*sut/sut*; n = 6) littermates were sacrificed by transcardial perfusion with ice-cold phosphate buffered saline and the left (A-F) hippocampus or (G-L) cortex rapidly dissected and snap-frozen in liquid nitrogen. The concentration of reduced and oxidized glutathione (GSH and GSSG) or cysteine (Cys and CySS) was determined by high performance liquid chromatography (HPLC) as described in Chapter 3 Materials and Methods. GSH, GSSG, Cys, and CySS levels were compared using an unpaired *t* test whereas GSH/GSSG or Cys/CySS ratios were compared using a Mann Whitney U test.

**A-L)** Bars [black bar (+/+) and open bar (*sut/sut*)] represent the mean μmoles/g tissue ± SEM of GSH (A and G), GSSG (B and H), Cys (D and J), CySS (E and K), or the ratio of GSH/GSSG (C and I) or Cys/CySS (F and L) in (A-F) hippocampus or (G-L) cortex. \**Sut/sut* female mice have a decreased hippocampal Cys/CySS ratio (*p* = 0.03; Mann-Whitney U test) and elevated GSSG levels (*p* = 0.01; unpaired *t* test) as compared to +/+ littermate controls.

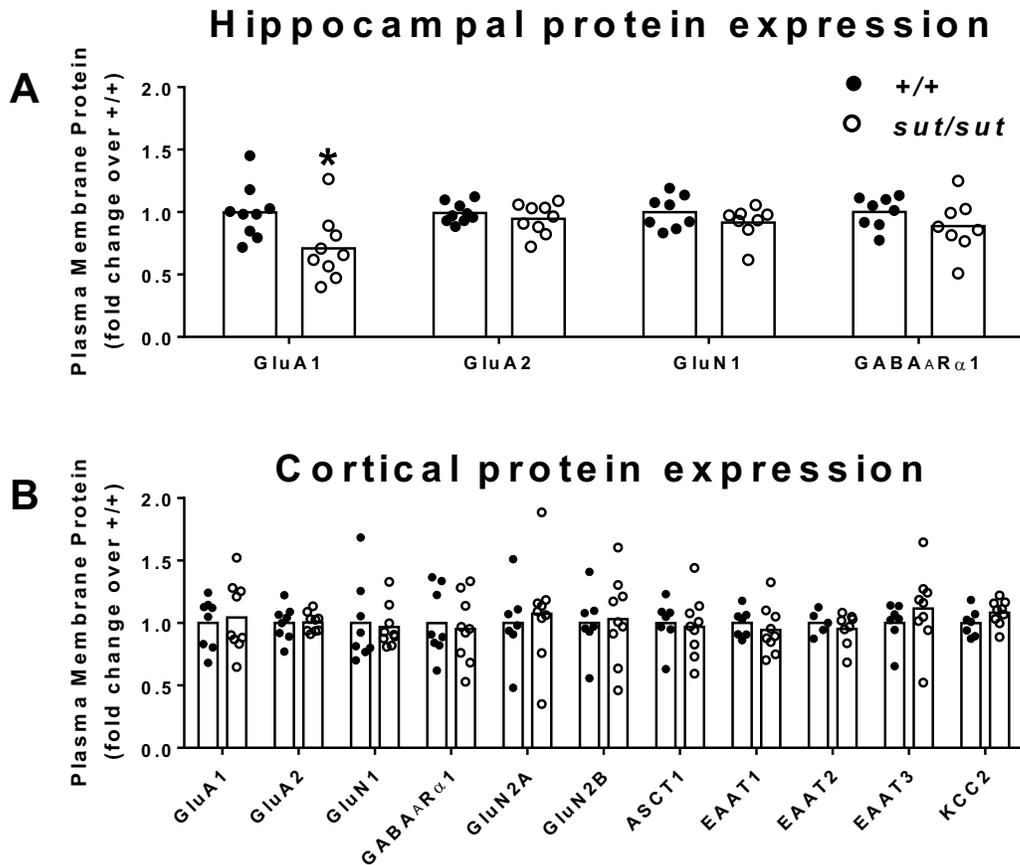

**Supplemental Figure S3: Female *SLC7A11<sup>sut/sut</sup>* hyper-excitability is not rescued by administration of N-acetylcysteine**

Naïve female *SLC7A11<sup>sut/sut</sup>* (*sut/sut*) littermates were administered 2-3 mg/ml of the cysteine prodrug N-acetylcysteine (NAC) (n = 9) or vehicle (water) (n = 9) *ad libitum* for eight days. On days 4-8, animals were acclimated to handling by performing mock daily intraperitoneal (i.p.) injections which consisted of inverting the mouse and rubbing its abdomen. On day nine, mice received a single dose of 42 mg/kg PTZ (i.p.). Seizure behavior was scored using a 5-point scale as described in Chapter 2 Materials and Methods. Data were pooled from three independent experiments performed over three months.

**A) Seizure Scores:** Each data point represents the maximal seizure score obtained by an individual female mouse during a 30 min observation period. Horizontal lines represent the median seizure score for each treatment. Seizure severity was compared using the Mann-Whitney U test.

**B) Convulsive index:** Bars represent the proportion (fraction within bars) of mice that experienced a convulsive seizure (seizure score  $\geq 3$ ) in A expressed as a % of total mice exposed to PTZ. Convulsive incidence was compared using Fisher's Exact test.

**Supplementary Figure S4: Comparison of plasma membrane protein expression in female *SLC7A11*<sup>+/+</sup> and *SLC7A11*<sup>sut/sut</sup> mice**

Plasma membrane protein levels in hippocampus or cortex derived from female *SLC7A11*<sup>+/+</sup> (+/+) or *SLC7A11*<sup>sut/sut</sup> (*sut/sut*) littermates were compared using Western blot analysis exactly as described for male mice in Chapter 3 Materials and Methods. Each data point [closed black circles (+/+; n = 7-9) or open circles (*sut/sut*; n = 5-9)] represents the level of hippocampal (B) or cortical (C) protein following normalization to their respective loading control (i.e., Na<sup>+</sup>/K<sup>+</sup> ATPase levels). Bars indicate the mean fold change over control (+/+), which was set to one. Hippocampal or cortical plasma membrane protein expression levels were compared using an unpaired *t* test on log-transformed data. An asterisk (\*) represents a significant between group difference ( $p = 0.0160$ ).

## Curriculum Vitae

### Sheila Shahidzadeh

107 College Place, Rm 110, Syracuse University • Syracuse, NY 13244

Cell Phone: 925-949-6887 • Work Phone: 315-443-2743

Email: [smshahid@syr.edu](mailto:smshahid@syr.edu)

### Education

---

- Ph.D. in Biology (neuroscience concentration)**, Syracuse University, Syracuse, NY **2018**  
**B.S. in Biopsychology (French minor)**, University of California, Santa Barbara. **2012**

### Research Experience

---

- PhD Student**, Syracuse University, NY. **2013– Present**  
Principal Investigator: Dr. Sandra J. Hewett  
Project: Understanding the role of system  $x_c^-$  in maintenance of the excitatory/inhibitory balance *in vivo*.
- Undergraduate Research Assistant**, University of California, Santa Barbara. **2011 – 2012**  
Principal Investigator: Dr. Steven Fisher  
Project: Investigating astrocyte morphological changes in response to a mouse model of retinal degeneration.
- Undergraduate Research Assistant**, University of California, Santa Barbara. **2010 – 2011**  
Principal Investigator: Dr. James Roney  
Project: Investigating the hormonal correlates of mate attractiveness.

### Honors and Awards

---

- Outstanding Teaching Assistant Award**, awarded to recognize teaching assistants who have made distinguished contributions to Syracuse University by demonstrating excellence in significant instructional capacities, The Graduate School, Syracuse University **April 2018**
- Certificate in University Teaching**, awarded by The Graduate School Future Professoriate Program at Syracuse University **April 2018**
- Best Graduate Student Poster Presentation**, Life Sciences Annual Symposium, Syracuse University Biology Department **April 2018**
- Travel fellowship recipient** (\$900), awarded by the Syracuse University Graduate Student Organization (\$400) and Neuroscience Program (\$500) to attend the 49th Annual Meeting of the American Society for Neurochemistry in Riverside, CA. **March 2018**
- Marilyn Kerr Scholarship** (\$31,750), awarded full stipend support by the Biology Department at Syracuse University **8/2017 - 8/2018**

<b>Travel fellowship recipient</b> (\$1400), awarded to attend the 26th Biennial International Society for Neurochemistry meeting in Paris, France from the International Society of Neurochemistry.	<b>August 2017</b>
<b>Travel fellowship recipient</b> (\$850), awarded by the Syracuse University Biology Department (\$350) and Graduate Student Organization (\$500) to attend the 46th Annual Society for Neuroscience meeting in San Diego, CA	<b>October 2016</b>
<b>Fellowship awarded to attend the ISN-JNC Flagship School</b> (\$900 + full-board accommodation) in Alpbach, Austria by the International Society of Neurochemistry-Journal of Neurochemistry (ISN-JNC).	<b>September 2016</b>
<b>Best Graduate Student Poster Presentation</b> , Neuroscience Research Day, Syracuse University	<b>April 2016</b>
<b>Travel fellowship recipient</b> (\$1100), awarded by the Syracuse University Graduate Student Organization (\$600) and Neuroscience Program (\$500) to attend the 47th Annual American Society for Neurochemistry meeting in Denver, CO.	<b>March 2016</b>
<b>Travel fellowship recipient</b> (\$350), awarded to attend the 45th Annual Society for Neuroscience meeting in Chicago, IL by the Biology Department, Syracuse University.	<b>October 2015</b>
<b>Admitted into the Women in Science and Engineering Future Professionals Program (WiSE-FPP)</b> , Syracuse University	<b>8/2015 - 8/2017</b>
<b>Attendee of "Workshop in Surgical Techniques in the Laboratory Mouse,"</b> held by the Jackson Laboratories in Paris, France.	<b>6/24–6/27/2014</b>
<b>Dean's List</b> , University of California, Santa Barbara.	<b>2008/2012</b>

## Presentations

---

### ***Invited talks***

"Altered brain excitability in system  $x_c^-$  null mice", Mclaughlin Research Institute, Great Falls, Montana **March 2018**

"Altered CNS excitability in system  $x_c^-$  null mice uncovered using the kainic acid model of status epilepticus", Astrocyte-neuron regulation of excitatory signaling workshop at the American Society for Neurochemistry meeting in Denver, Colorado. **March 2016**

### ***Posters***

**Shahidzadeh S.M.**, Hewett J.A., Hewett S.J. Sex differences in redox environment and neuronal morphology occur in association with enhancement of excitability in system  $x_c^-$  null mice. Presented at the American Society for Neurochemistry Meeting in Riverside, CA. March 2018.

**Shahidzadeh S.M.**, Hewett J.A., Hewett S.J. Altered neuronal excitability in system  $x_c^-$  null mice in vivo uncovered by chemoconvulsant challenge. Presented at the International Society for Neurochemistry Biennial Meeting in Paris, France. August 2017.

**Shahidzadeh S.M.**, Hewett J.A., Hewett S.J. System  $x_c^-$  null mice are resistant to pentylenetetrazole kindling. Presented at the Society for Neuroscience Meeting in San Diego, CA. November 2016.

**Shahidzadeh S.M.**, Hewett J.A., Hewett S.J. Altered CNS excitability in system  $x_c^-$  null mice uncovered using the kainic acid model of status epilepticus. Presented at the American Society for Neurochemistry Meeting in Denver, CO. March 2016.

**Shahidzadeh S.M.**, Hewett J.A., Hewett S.J. Role of system  $x_c^-$  in the pentylenetetrazole model of temporal lobe epilepsy. Presented at the Society for Neuroscience Meeting in Chicago, IL. October 2015.

## **Teaching Experience**

---

**Lecturer**, Biology Department, Syracuse University, Syracuse, NY

“**Synaptic Plasticity**” Advanced Neuroscience course. Syracuse University. (2017-2018, yearly).

“**The Blood Brain Barrier**” Advanced Neuroscience course. Syracuse University. (2015-2017, yearly).

**Teaching Assistant**, Biology Department, Syracuse University, Syracuse, NY

**Introduction to Biology** (BIO 121); two semesters. (Fall 2013/2014).

**Anatomy and Physiology I and II** (BIO 216); two semesters. (Spring 2014/fall 2015).

**Biology of Adaptive Behavior** (BIO 414); one semester. (Spring 2015).

**Developmental Biology** (BIO 504); two semesters. (Spring 2016/17).

**Cell Biology** (BIO 327); one semester. (Fall 2016).

**Advanced Neuroscience** (BIO 407/607); three semesters. (Spring 2015/16/17).

## **University Service**

---

**Ad hoc Reviewer**, Brain Research, (May 2017 – Present).

**Ad hoc Reviewer**, Neurochemistry International, (February 2018 – Present).

**Graduate Representative**, Graduate Recruitment Committee, Biology Department at Syracuse University (May 2016 – May 2017).

**Graduate Scientific Member**, Institutional Animal Care and Use Committee (IACUC) at Syracuse University (June 2016 – September 2018).

**Vice President**, Biology Graduate Student Organization (BGSO), Syracuse University (2014 – 2016).

**Vice President**, National Society of Collegiate Scholars, UCSB Chapter (2010-2012).

## Professional Training

---

**Postdoctoral Tenure-Track Boot Camp**, sponsored by Women in Science and Engineering at Syracuse University. June 2018.

**Future Professoriate Program (FPP) Workshop**, sponsored by Syracuse University FPP, White Eagle Conference Center, New York. May 2017.

**Astrocyte-Neuron Regulation of Excitatory Signaling Workshop**, the 47th ASN meeting, Denver. March 2016.

**Neurobiology of Disease Workshop**, the 44th SfN meeting, Washington, DC. November 2014.

**Workshop on Surgical Techniques in the Laboratory Mouse**, The Jackson Laboratory, Paris, Fr. June 2014.

## Professional Associations

---

**Member**, American Society for Neurochemistry, 2016 - Present

**Member**, International Society for Neurochemistry, 2016 - Present

**Member**, Institutional Animal Care and Use Committee, 2016 - Present

**Member**, Women in Science and Engineering Future Professionals Program, 2015 - Present

**Member**, Society for Neuroscience, 2014 - Present

**Member**, Biology Graduate Student Organization, 2013 - Present

**National Society of Collegiate Scholars**, UCSB Chapter, 2010 – 2012

**Psi Chi National Honor Society in Psychology**, UCSB Chapter, 2010 – 2012

## Technical Skills

---

Animal behavioral studies including the kainic acid model of status epilepticus, pentylenetetrazole kindling model of epileptogenesis, and chemoconvulsant induced acute seizures.

Transcardial perfusion of rodents and tissue (brain) sectioning.

Histochemical staining and stereological analysis; Golgi-Cox stain, Timm stain, Nissl stain, and Fluorojade-C stain.

Primary cell culture (purified neurons and astrocytes).

q-PCR, Western blot, and immunohistochemistry

Skilled in major professional software (Word, PowerPoint, Excel, EndNote, Photoshop) as well as GraphPad Prism, Adobe Illustrator, and ImageJ (NIH).
