(Dated: March 6, 2008)

We study the minimum-energy configuration of a $d$-dimensional elastic interface in a random potential tied to a harmonic spring. As a function of the spring position, the center of mass of the interface changes in discrete jumps, also called shocks or “static avalanches”. We obtain analytically the distribution of avalanche sizes and its cumulants within an $\epsilon = 4 - d$ expansion from a tree and 1-loop resummation, using functional renormalization. This is compared with exact numerical minimizations of interface energies for random field disorder in $d = 2, 3$. Connections to the Burgers equation and to dynamic avalanches are discussed.

In numerous systems, the equilibrium or non-equilibrium response to perturbations is not smooth and involves jumps, avalanches, or bursts. In systems at the brink of instability, with many metastable states, it is often self-organized and critical with power-law tails for the probability of large events. This is observed ubiquitously in systems with heterogeneities, such as Barkhausen noise and hysteresis in magnets, field response of superconductors, contact line of fluids, cracks, granular matter, dry friction and earthquakes. Sandpile automata \cite{1} and between sandpile models and loop-erased walks studied as simple models for these phenomena. Relations between sandpiles and periodic interface depinning \cite{7, 11} and between sandpile models and loop-erased walks \cite{6, 11, 12} have proved fruitful, especially in $d = 2$, where conformal field theory can be used \cite{8}. Despite much effort it has proven difficult to obtain analytical results, e.g. for the distribution of the size $s$ of avalanches (defined below), except in mean-field models for sandpiles \cite{10} and for random field Ising magnets \cite{3} as well as for a toy model for avalanches at depinning \cite{2}, which all yield $P(s) \sim s^{-\tau}$ with $\tau = 3/2$. Scaling arguments for sandpiles \cite{1, 7} and for depinning \cite{11}, were developed together with numerical analysis \cite{3, 12, 13}. The Functional Renormalization Group (FRG) theory for pinned systems has led to detailed predictions for e.g. the roughness of interfaces but, until now, has failed to describe discontinuous jump processes \cite{14, 15, 16}. Hence it remains an outstanding issue to find a limit where mean field theory is valid, prove this, and to develop a controlled field-theoretic expansion around it. It should allow to clarify the differences between equilibrium and non-equilibrium avalanches, recently questioned in a model for magnetic hysteresis \cite{17}.

The aim of this Letter is to provide a first analytical calculation of the distribution of avalanche sizes in a static, equilibrium setting, using FRG, and to compare with numerical calculations. It opens the way to a closely related calculation for depinning \cite{18}. As demonstrated in our previous work \cite{19}, a model which allows a precise FRG treatment and comparison with numerics, both in statics and dynamics, consists of an elastic interface in a random potential, parameterized by a (scalar) height field $u(x)$, and submitted to an external parabolic well, i.e. a spring, centered at $u = w$, \begin{equation}
\mathcal{H}[u; w] = \int d^d x \frac{1}{2} (\nabla u(x))^2 + V(x, u(x)) + \frac{m^2}{2} (u(x) - w)^2.
\end{equation}

We are interested in energy minimization as $w$ is varied in a given realization of the random potential $V(x, u)$. We denote $\tilde{V}(w) = \min_{u(x)} \mathcal{H}[u; w]$ the optimal energy and $u(x; w)$ the optimal interface position. The force per unit volume exerted by the spring is $\tilde{V}'(w) = m^2[w - u(w)]$, where $u(w) := \tilde{L}^{-d} \int d^d x u(x; w)$ is the center-of-mass position and $\tilde{L}$ the volume of the system. We study the three important universality classes for disorder, with short range (random bond, RB), long range (random field, RF) or periodic disorder correlator (random periodic, RP). Their definitions can be found in \cite{15, 13, 16} and in standard papers on pinning \cite{20} and FRG \cite{14, 15, 16}.

Although we often use the language of dynamics, one should emphasize the difference between the static problem studied here, where the interface finds the global energy minimum for each $w$, and the dynamic one, where $w(t)$ grows very slowly, and the interface visits a deterministic sequence of metastable states. In the scaling limit $m \to 0$, on which we focus here, the first case is about interface configurations of zero-temperature equilibrium, studied in \cite{19}, whereas the latter one is about critical depinning, studied in \cite{24, 25}. In the statics $u(w)$ is a (single-valued) function, while it shows some history dependence at depinning. Despite these differences, depinning and statics are close cousins and some differences within the FRG are found only beyond one loop \cite{16}.

As shown previously \cite{14, 15, 19, 20, 22, 23}, the optimal interface is statistically self-affine with $(u(x) - u(0))^2 \sim |x|^{2\zeta}$ and a roughness exponent $\zeta$ which depends on the class of disorder, and with a $\epsilon = 4 - d$ expansion \cite{16}; $\zeta = \epsilon/3$ for RF, $\zeta = 0$ for RP, and $\zeta = 0.208 + 0.00676 \epsilon$ for RB (and $\zeta = 2/3$ in $d = 1$). This holds for scales $L_r < L < L_m$, where $L_r$ is the Larkin length (here of the order of the microscopic cutoff) and $L_m \sim 1/m$, the large
scale cutoff induced by the harmonic well. It is useful to picture the interface as a collection of \((L/L_m)^d\) regions pinned almost independently.

We found that \(u(x;w)\) is an increasing function of \(w\) which can be decomposed into smooth parts, negligible in the scaling limit \(m \to 0\) and jumps (alias "shocks" or "static avalanches") as \(u_x(w) = \sum_i S_i^2 \theta(w - w_i)\), where \(S_i = \int d^d x S_i^2\) is the size of the shock or avalanche labelled \(i\), and \(\theta(x)\) the unit-step function. The avalanche-size distribution, defined from an average over samples,

\[
\sum_i \delta(S - S_i) \delta(w - w_i) = \rho(S) = \rho_0 P(S) ,
\]

can equivalently be defined from a translational average in a given sample. Here \(P(S)\) is the normalized size distribution and \(\rho_0 dw\) the average number of shocks in an interval \(dw\). The scaling ansatz

\[
\rho(S) = L^d m^p S^{-\tau + \zeta} \tilde{p}(S m^{d+\zeta}) \tag{3}
\]
is shown below to hold within the \(\epsilon\) expansion and verified by our numerics. The constraint \(u'(w) = 1\) relates the shock rate to the first moment \(M_1 = \int dS S^n P(S)\) denotes the normalized moments. It implies for \(\tau < 2\) the exponent relation \(\rho = (2 - \tau)(d + \zeta)\). The distribution is qualitatively different for \((i)\) \(\tau < 1\) when a unique scale \(S_m \sim m^{-(d+c)}\) exists, i.e. \(\rho(S) = S_m^{-1} \tilde{p}(S/S_m)\), and \((ii)\) \(1 < \tau < 2\), where \(P(S) = C \rho_0^{-1}(S/S_0)^{-\tau} f(S/S_m)\),

\[
P(S) = C \rho_0^{-1}(S/S_0)^{-\tau} f(S/S_m) , \tag{4}
\]

typical avalanches are of the order of the microscopic (UV) cutoff \(S_0\), while moments \(\langle S^p \rangle\) with \(p > \tau - 1\) are controlled by rare avalanches of size \(\sim S_m\), the large-scale cutoff.

As discussed recently \cite{24}, shocks for manifolds are a natural generalization of shocks in decaying Burgers turbulence, seen as their \(d = 0\) limit (with, for the RF case, \(\tau = 1/2\) in that limit). The force field \(V'(w) = m^2[w - u(w)]\) generalizes the Burgers velocity field. Its \(n\)-point connected correlation \(V'(w_1) \ldots V'(w_n)\) obeys FRG equations, which generalize the hierarchies of Burgers multi-point correlations. Shock-size moments can be extracted from their non-analytic part: E.g. the second moment is contained in the cusp of the disorder correlator \(\Delta(w) = \tilde{C}'(w,0)\) of the FRG, as seen from the relation \(\rho^{-1} L^{-d} \Delta''(w) = \tilde{u}'(w) w(0) = L^{-2d} \sum_i S_i^2 \delta(w - w_i)\delta(w)\) smooth function, which upon integration gives \(-2 \Delta(0^+) = m^2 \langle S^2 \rangle / \langle S \rangle\). This generalizes to higher cumulants \(\tilde{K}'(n)(w) = m^{2n} L^{(n-1)d} \tilde{u}'(w) w(0)^n\) (the linear cusp of \(K(3)\), measured in \cite{17}, generalizes Kolmogorov’s law). Hence we can compute the avalanche-size distribution using the generating function

\[
L^{-d} (e^{\lambda L^d [u(w) - w(0)] - 1}) = Z(\lambda) w + O(w^2)
\]

for \(w > 0\). It assumes a linear cusp (i.e. a finite density of shocks) and generalizes to depinning \cite{18}.

We have computed the leading non-analyticity of the functions \(\tilde{K}'(n)(w)\) \cite{28} from (i) a Legendre transform of the replicated effective action \(\Gamma\) computed order by order in \(\epsilon\); (ii) a direct perturbative expansion without replica. The calculation is more involved than usually for FRG: the size distribution already at order \(O(\epsilon^0)\) requires a summation of all tree diagrams. The latter could be termed mean field, but with the proviso that the scale of \(S\) involves \(\Delta(0^+)\) computed to \(O(\epsilon)\). Here we compute to order \(O(\epsilon)\), which amounts to sum all trees and single loops; for details see \cite{27}. The main result is that \(Z(\lambda)\) satisfies a remarkable self-consistent equation to one loop

\[
\tilde{Z}(\lambda) = \lambda + \tilde{Z}(\lambda)^2 + \alpha \sum_{n \geq 3} (n + 1) 2^{n-2} i_n \tilde{Z}(\lambda)^n , \tag{5}
\]

where \(Z(\lambda) = m^4 \langle \lambda m^{-4} | \Delta(0^+) \rangle - \lambda\), \(i_n = \langle n \rangle (k^2 + 1)^{-n}\), \(\alpha = -i \tilde{I}_2 m^{-2} \Delta''(0^+)\). It can graphically be written as

\[
\text{FIG. 1: Example of a diagram at MF level, as generated by Eq. (6)}
\]

The type of resummed diagrams is presented on figure. Since \(\alpha = O(\epsilon)\), to leading order one solves \(\tilde{Z}(\lambda) = 0\) setting \(\alpha = 0\). This yields \(\tilde{Z}(\lambda) = \frac{1}{2} [1 - \sqrt{1 - 4\lambda}]\), identical to the generating function of the number of rooted binary planar trees with \(n\) leaves \cite{29}, and a size distribution, with \(\tau = 3/2\):

\[
P(S) = \frac{\langle S \rangle}{2} \tilde{P}(S) = \frac{\langle S \rangle}{2} \tilde{S}^{-1/2} S^{-3/2} e^{-S/(4S_m)} . \tag{7}
\]

This is valid for \(S \gg S_0\), such that \(\tilde{K}'(3)(w)\) the moments with \(p > \frac{1}{2}\) satisfy \(\langle S^p \rangle / \langle S \rangle = a_p S_m^{p-1}\) with \(a_p = 2^{2p-2} \pi^{-1/2} \Gamma(p - \frac{1}{2})\), independent of the non-universal small-scale cutoff \(S_0\). Hence the rigorous summation of tree diagrams in the FRG yields the same \(P(S)\) as that of a mean-field toy model for dynamic avalanches.
and that of mean-field sandpiles \cite{10}. In addition, since the FRG is a first principle method, it predicts 
\( S_m = cm^{-d-\epsilon} \) where \( c = (\epsilon f_2)(\Delta'(0^+)) \) is obtained from the FRG fixed point for the rescaled correlator 
\( \Delta(u) = (\epsilon f_2)m^{d-\epsilon+2\epsilon\alpha} \Delta(u^{-\epsilon}) \) and depends on the 
universality class \cite{27}. Since \( \tau > 1 \), the scale \( (S) \sim S_m^{-1} \) remains undetermined and UV cutoff dependent. Eq. \( \text{(6)} \), 
seen as a convolution equation for \( P(S) \), may allow to put the physical picture in \cite{2} on a more rigorous footing.

To next order in \( \epsilon \) we solve Eq. \( \text{(6)} \) which includes higher branchings with a universal dimensionless rate 
\[
\alpha = -\frac{1}{3} (1 - \zeta_1) \epsilon \quad (8)
\]
at the fixed point, where \( \zeta = \zeta_1 \epsilon + O(\epsilon^2) \) and \( i_n = 1/2(n-1)(n-2) \) in \( d = 4 \). It yields 
\[
\dot{Z}(\lambda) = \frac{1}{2} \left[ 1 - \sqrt{1 - 4\lambda} \right] + \frac{\alpha}{4\sqrt{1 - 4\lambda}} \left[ \log(1 - 4\lambda) \times \right. \\
\left. \times (3\lambda + \sqrt{1 - 4\lambda - 1}) - 2(2\lambda + \sqrt{1 - 4\lambda - 1}) \right] + O(\epsilon^2) \quad , (9)
\]
from which one can calculate the universal ratios: 
\[
r_n := \langle S^{n+1} \rangle / \langle S^{n-1} \rangle \langle S^n \rangle^{-2} = \frac{2n - 1}{2n - 3} - \frac{\epsilon}{3} (1 - \zeta_1) \frac{n \Gamma(n - \frac{3}{2})}{(2n - 3)^2 \Gamma(n - \frac{1}{2})} + O(\epsilon^2) \quad , (10)
\]
for any real \( n > 3/2 \), with \( \zeta_1 = 1/3 \) for RF, \( \zeta_1 = 0 \) for RP and \( \zeta_1 = 0.283 \) for RB. Upon inversion of the Laplace transform one finds: 
\[
P(S) = \frac{(S)}{2\sqrt{\pi}} S_m^{-\tau} A S^{-\tau} \exp \left( C \sqrt{\frac{S}{S_m}} - B \left[ \frac{S}{S_m} \right]^\delta \right) \quad (11)
\]
for \( S >> S_0 \), with \( C = -\frac{1}{2} \sqrt{\pi} \alpha, \quad B = 1 - \alpha(1 + \frac{6}{S}) \), 
\( A = 1 + \frac{1}{8}(2 - 3\epsilon)\alpha, \quad \gamma_E = 0.577216 \), and exponents: 
\[
\tau = \frac{3}{2} + \frac{3}{8} \alpha = \frac{3}{2} - \frac{1}{8} (1 - \zeta_1) \epsilon + O(\epsilon^2) \quad (12)
\]
\[
\delta = 1 - \frac{\alpha}{4} = 1 + \frac{1}{4} (1 - \zeta_1) \epsilon \quad . \quad (13)
\]
Note that the decay of large avalanches becomes stretched (sub)exponential (in \( d = 0 \) for RF, \( \delta = 3 \)).

\begin{table}[
\centering
\begin{tabular}{|c|c|c|c|}

RF & \( r_2 \) & \( r_3 \) & \( r_4 \) \\
\hline
mean field & 3 & 1.67 & 1.4 \\
\hline
\( d = 3, \text{eq. (10)} \) & 2.33 & 1.54 & 1.34 \\
\hline
\( d = 3, \text{numerics} \) & 2.25\pm0.05\pm0.2 & 1.48\pm0.04\pm0.14 & 1.27\pm0.02\pm0.13 \\
\hline
\( d = 2, \text{eq. (10)} \) & 1.66 & 1.42 & 1.28 \\
\hline
\( d = 2, \text{numerics} \) & 1.95\pm0.02\pm0.06 & 1.38\pm0.02\pm0.06 & 1.21\pm0.02\pm0.06 \\
\hline
\end{tabular}
\caption{Universal amplitude ratios with statistical and systematic errors (in this order) for numerics; there is a systematic error since the measured ratios decrease with decreasing mass. For \( d = 2 \), the decrease which we take as systematic error was measured from masses \( m^2 = 0.025 \), \( m^2 = 0.00125 \), and \( m^2 = 0.000625 \) (whose values are given). For \( d = 3 \), the corresponding one is measured for the two smallest masses \( m^2 = 0.0025 \) and \( m^2 = 0.00125 \) (with values from the latter).}
\end{table}
We note that our result for $\tau$ agrees to $O(\epsilon)$ with the conjecture
\[ \tau = 2 - \frac{2}{d + \zeta} \] (14)
equivalent to $\rho = 2$. It was presented for depinning [11] and for the $\tau_s = 4/3$ exponent of the number of topplings in a sandpile model in $d = 3$ [2], which may be compared to CDWs. Since assumptions leading to (14) are not rigorous, our first-principle calculation confirms this to one loop, and leaves open the possibility of higher-loop corrections. Our results are straightforwardly extended to the case of LR elasticity [27].

Exact numerical calculation of minimum-energy interfaces has been performed using the discrete models and algorithms as described in [19] were details can be found. The (corrected) distribution is presented on figure 3 for the example of RF in $d = 2$. We measure
\[ \tau = 1.25 \pm 0.02 \, (\text{RF, } d = 2) , \quad \tau = 1.37 \pm 0.03 \, (\text{RF, } d = 3) \] (15)
This is compatible with eq. (14). Note that the extra stretched-exponential term $C$ in (11) (which could not be interpreted as summation of a pre-exponential power) leads to a bump which can clearly be seen in the numerics on figure 3. Finally we have measured (see Fig. 1) the distribution of the intervals between successive jumps (occurring at positions $w = w^i$) and found it to be very close to a pure exponential.

To conclude, using Functional RG we have performed an expansion around the upper critical dimension to obtain the avalanche or shock distribution in the statics. It compares well with the numerics. Preliminary results [18] indicate that the above mean-field and 1-loop results also hold for depinning (with the corresponding values for $\zeta$); 2-loop calculations are in progress to further check the conjecture (14) and quantify the difference between static and dynamic avalanches.

We acknowledge very useful discussions with Karin Dahmen and Andrei Fedorenko and support from NSF Grants 0109164 and 0219292 (AAM) and ANR program 05-BLAN-0099-01 (PLD and KW).

[26] A. Rosso, P. Le Doussal and K.J. Wiese, cond-mat/0610821
[29] Cumulants and moments have the same non-analyticity.
[30] Equals the number of rooted planar trees with $n+1$ bonds and arbitrary coordination, the Catalan numbers.
[31] Note that for $\lambda \to \infty$, $Z(\lambda) \sim -S_m^{-2} |\lambda|^{-1}$ in the scaling regime and should converge to $-1/S_0 \sim -S_0^{1-r} S_m^{-2}$ for $\lambda \sim 1/S_0$ in the UV cutoff regime.
